The author states that in fractures involving the knee joint (encountered most frequently during the third and fourth decades of life) there is danger of arthritis if perfect reduction is not obtained.

Fractures of the knee joint, of recent occurrence may be divided into three groups: (1) linear fractures without displacement, (2) fractures with complete separation of the broken fragment and (3) compression fractures. Fracture of one condyle is observed more frequently than of both condyles of the femur. The lateral condyle is fractured twice as frequently as the medial condyle and the lateral half of the tibial plateau breaks approximately five times as frequently as does the medial half.

The introduction of vitallium, which is better than other materials, and the use of plaster which minimizes the danger of infection, are to be great advances in treatment, but the author is convinced that surgical treatment does not decrease the period of functional disability. On the other hand manually closed reduction has, as a rule, effect on the fractures in question because of the small size of the fragment. The reduction is more difficult if the fracture is associated with laceration of the collateral ligaments or of the capsule. In fractures of one of the femoral condyles it is nearly impossible to correct the rotation of the fragment along the transverse axis.

If open reduction is required, the operation is delayed for a few days, to minimize the danger of infection. Operation is done under either anesthesia with or without the intravenous injection of ether.

A longitudinal parapatellar incision slightly to its lower portion on the medial or lateral side is used for the reduction of a fracture of the condyle. It is advisable to refrain from incision of the patellar tendon at the tibial tuberosity.

The author cautions against the employment of a horizontal or an oblique incision for arthroscopy because of the possibility of injury to the collateral ligaments and the median portion of the cutaneous branch of the saphenous nerve with the formation of a neuroma or a zone of anesthesia. Three or four nails of nonoxidizable material are sufficient to immobilize the fragment.

A fracture of the tibial plateau is much more difficult to reduce, especially if the posterior part of the tibial epiphysis is injured. The same procedure is recommended as for the open reduction of a fracture of a femoral condyle. In patients with a posterior marginal fracture the incision is made on the anterior aspect of the articulation, in the medial-lateral region according to the site of the fracture. A wide exposure with due attention to the collateral ligaments is advocated. Five to 10 cm. in diameter are employed. Complete hemostasis is essential. A rubber drain is inserted into the upper end of the wound. The extremity is immobilized with the knee flexed 30 to 35 degrees. Extension is maintained for a period of 2 to 3 weeks to allow the wound to heal and to reduce infection which is enhanced by early motion.

In conclusion the author states that if the patient does not show signs of a grave condition of the patient is good, gives the best results. *JOSEPH E.*

ORTHOPEDICS IN GE

A Study of Vascularization of the Importance in Traumatology (La circolazione del radio nella traumatologia) ROMANO T *Med. 11* 362.

The importance of blood vessels is of great importance because of.

processes following various osseous lesions such as acute and chronic osteomyelitis and their function in the regeneration of bone following fractures.

The author has studied the distribution of blood vessels within the radii of cadavers. A 2 per cent gelatin solution with the addition of either Prussian blue or Congo red was employed for the injection of the brachial artery after preliminary ligation of the radial and ulnar arteries at the wrist. The radius was exarticulated placed in a 5 per cent formalin solution for 50 hours, rinsed in water and immersed into a 6 per cent nitric acid solution (for the purpose of decalcification) in which it remained from 25 to 34 days according to the age of the patient. Sections in frontal and sagittal direction were made and placed in pure glycerin for a period of 30 hours to make them translucent.

The entire material was divided into three groups according to the age of the patients i.e. 6 to 25, 26 to 40 and 41 to 72 years.

Inspection of the specimens demonstrated a relatively poor vascularization of the middle third of the bone as compared with the upper and lower thirds.

The difference becomes more marked with advancing age. According to Lenche, the circulatory factors are of greatest importance in the genesis of the osseous substance. Vascular deficiency impairs the active hyperemia which favors pathologic ossification. Poor blood supply is responsible for an unsatisfactory regeneration of bone tissue in the femoral neck and in the vertebral bodies.

The relatively poor blood supply of the radial diaphysis is responsible for retarded consolidation after fracture or a tendency to the formation of a pseudarthrosis. Inasmuch as it is impossible to augment the number of blood vessels the author believes that an effort should be made to increase the blood supply by producing hyperemia by means of the application of heat, Bier's passive congestion or Beck's operation.

JOSEPH K. NARAY, M.D.

Reconstruction of Opposition Digits for Mutilated Hands. B. K. RAWK and A. R. WATKINSELD
Austral. N. Zealand J. Surg. 1948, 17, 172

During a period of 4½ years in an Army plastic surgery unit while 630 patients with face injuries were treated 403 patients with hand injuries were also treated. In 55 per cent of the latter group gross mutilations had occurred. The 'pinch' or opposition function in a normal hand involves essentially the function of a normal thumb. For this to be effective in a mutilated hand three considerations must be met: (1) the thenar muscles must be present and active in a functioning state of integrity at attachment and innervation (2) there must be an adequate length of projecting thumb (3) there must be present an adequate length of finger or fingers to which the remaining length of thumb can become apposed in the movements of opposition and flexion.

The author advocates a four-stage operation as the most satisfactory means of obtaining an opposition digit.

The raising of a tube pedicle (stage 1) Under general or local anesthesia a standard tube pedicle is made in a convenient position on the abdomen or in the acromipectoral region.

Attachment of the pedicle to the hand (stage 2) Under general anesthesia the appropriate end of the tube pedicle is detached from the abdomen or chest. The tubing of a flap and its attachment to the stump at a single stage are not advised.

Detachment of the pedicle from the abdomen (stage 3) Usually only a small amount of local anesthetic solution is required for this stage. The pedicle is severed from the abdomen to leave the length required on the hand for the opposition digit. This stage, although it involves the simplest operation is the most important hurdle of the whole procedure.

The bone graft (stage 4) Under general anesthesia the longitudinal suture line of the pedicle extension is reopened about one-half to one inch short of the distal end and if necessary the incision is extended on to the normal tissues of the hand. By turning aside the pedicle extension the bone stump is exposed through the wound. This is trimmed of sclerotic bone and its medulla is gouged out with a small spoon to about half an inch. Cancellous bone from the iliac crest is used as the bone graft. One end is fashioned as a peg to be dowelled into the stump of metacarpal or phalanx the other end is rounded. It is approximately rectangular in section with corners rounded. The graft is arranged in the core of the pedicle and pegged into the open bone stump with as little disturbance as possible. The digit is splinted in correct position by a complete plaster which is left undisturbed for about a month.

After care After 1 month the plaster is taken off and sutures are removed. Daily and slowly increasing active exercises are commenced but between times a protection splint is worn.

Reconstruction of paired opposition digits Hands devoid of all fingers can still be rendered useful so long as some actively mobile thumb metacarpal bone remains. One mobile digit on the thumb base and one fixed digital extension from the palm can be made on the principle already described.

A slow distal extension of sensory appreciation in the grafted skin area is noted from month to month. The results show that any degree of hand function or movement which can be effected is much better than an amputation stump and superior to an artificial hand.

C. FRED GOEDINGER, M.D.

The Synovial Membrane of the Knee Clinical and Experimental Study (Le membrane synoviale du genou. Étude clinique et expérimentale) R. SORU
Rev. belge path. 1947 18 Supp. 1

The author does not attempt a solution of the many controversial problems of the pathology of the synovial membrane of the knee but aims merely to add to the scant clinical and experimental knowledge of this organ. The literature is carefully reviewed and followed by a description of the author's own observations and experiments. For the study

of the normal histologic structure of the organ specimens were taken from stillborn infants young infants dying of pneumonia and chloera and from amputations in patients of various ages. No cases were included in which the bone or cartilage was affected.

The pathology of the soft tissues of the knee is discussed under four headings, namely rupture of the meniscus, hemarthrosis, chronic villous hypertrophic arthritis and Hoffer's disease. The latter, classically described as a primary transformation of the subarticular fat pad, is not considered as an entity by the writer but merely as representing the symptoms of ruptured meniscus, villous arthritis or some other disease such as chondromatosis or tumor.

An attempt was made to reproduce these lesions in animals in order to ascertain the modes of reaction of the synovial membrane and the laws governing its reaction to given stimuli.

The normal synovial membrane was found to have two layers, one fusing with the other without any definite delimiting line. The intima was largely unicellular with a few scattered histocytes. The external layer at the level of the anterior fat pad was composed chiefly of fat cells and was occasionally invaded by collagenic fibrils. This fibrous layer was always discrete and there was no inflammatory element. It was looked upon as a sign of aging. Opposing theories are reviewed. Studies on the rabbit revealed that the histologic structure of the synovial membrane in this animal was identical with that in man.

With a view toward supplementing the previously reported histologic studies on meniscal lesions, 28 biopsy specimens were taken from a series of 106 cases of surgically verified lesions of the fibrocartilage. Three stages of the pathological process are described.

1. A preliminary stage with predominantly traumatic changes in the synovial membrane. By the second month anatomical reaction is stable and lasts as long as the lesion of the fibrocartilage persists (for 34 years in one case).

2. The second or florid stage is about 6 months, and is characterized by intense cellular activity and progressive fibrosis, but no inflammatory reaction.

3. The third or residual stage is until the meniscal rupture is treated by either partial or total removal of the organ, and presents symptoms similar to those of the florid stage but of a more chronic type. The signs of synovial activity subside but the fibrosis becomes organized and collagenic tracts tend to become systematized. There is also a varying degree of plasmocyte infiltration, occasional mononuclear and in rare instances, with nodular forms. Both in man and in animals the changes in the synovial membrane following rupture of the meniscus indicate a distant reaction. Apparently the synovial membrane is particularly sensitive to intra-articular disturbances.

The florid and residual stages of synovial membrane reaction to hemarthrosis in man and animals are likewise described. The effusion of blood into a joint has only a transitory and very superficial effect on the synovial membrane, leaving no lasting trace.

The identical histologic aspects of the synovial membrane in hypertrophic villous chronic arthritis in man and in animals indicate an identical mechanism, a reaction comparable to the Arthus phenomenon occurring in the joint. In the florid stage the dominating process is a waxy degeneration of the basic substance with massive infiltration of plasmocytes and leucocytes. Together with the fibrocytes, these cells form the characteristic Klinger nodules. There are also signs of connective tissue activity, replacement of fatty tissue by fibrous tissue and increased vascularization.

The changes in the synovial membrane produced experimentally in rabbits by repeated injections of protein are similar to those observed in man, and suggest that the Arthus phenomenon leaves a residual extracellular condensation which lasts a long time and permits of a reaction to revive the symptoms.

It is shown that periparturition is the most commonly encountered reaction and is found in normal aging in the florid stage of meniscal rupture in hemarthrosis in Berger's arthritis and following artificial injection of homoplasma into the joint of a non-sensitized animal.

The intra-articular irritant is not therefore to be regarded merely as a filter but represents an active organ, extremely sensitive to the slightest mechanical, chemical or irritant stimulus. This latent function of the synovial membrane constitutes an abnormal response to stimuli acting under special conditions similar to that obtained in connective tissue under the same conditions.

Examination of the synovial membrane per se yields no histological lesion but a degree plus the presence of meniscal element begins to differentiate one pathological condition from another, especially during the florid stage.

In meniscectomy and related reactions, the collagenous reaction is progressive and highly systematized. There is no infiltration.

In the course of an effusion the fibrous formation is very moderate but polymorphous and mononuclear appear while histocytes collaborate to eliminate substances scattered through the joint.

If proliferation of connective tissue is marked during the course of the Arthus phenomenon, it is accompanied by plaques of waxy degeneration and, above all, by a massive invasion of the tissue by fibrocytes and monocytes.

infiltration somewhat similar to that seen following mechanical insults develops. Similar convergence phenomena have been observed in histology.

The reaction of the entire joint to a meniscal lesion, the facility of resorption of hemarthroses, the chronicity of chronic arthritis and the termination of initially different conditions in residual arthritis have all been observed clinically. By the more complicated but also more detailed and accurate methods of microscopic analysis these findings can be histologically confirmed. A tiny biopsy specimen suffices.

The terms synovial activity, fibrosis and infiltration are defined, and a table is presented showing the clinical and experimental findings in the synovial membrane in the diseases mentioned. Figures showing sections from the synovial membrane of the normal knee and of operative specimens as well as photographs illustrating cases and a list of references are included. EDITH SCHWARTZ MOORE.

Anatomy of the Foot and Examination for Its Disorders. ROBERT J. JOHNS. *Osney St.* 1947. 4. 314

The author presents a very comprehensive description of the anatomy of the foot—its bones, muscles, ligaments, blood supply and nerve supply. A carefully taken history including important facts in the family and past history as well as an accurate and detailed investigation into the complaints for which advice is sought should precede inspection of the feet.

A systematic routine examination should be regularly carried out with the feet about 4 inches apart. No examination is complete without roentgenogram and laboratory studies. A record should be made of the following: (1) swelling, generalized or localized; (2) vascular conditions of the skin; (3) knock knee; if present, record the distance between the internal malleoli with the femoral condyles touching; (4) how legs recoil; the distance between the internal condyles, crests of the tibia, and the internal malleoli with the feet together; not only rickets but Paget's disease, Charcot's knees and arthritis cause bowing; (5) torsion of the tibia, this should be looked for and when severe must be corrected; (6) hallux valgus usually associated with primus varus deformity, this is a painfully disabling condition which frequently

exists in an otherwise strong healthy worker; a painless useful foot may result from a relatively simple Keller type of operation but such a foot is not ideal for heavy work requiring long periods of standing; (7) calluses and hammer toe deformities, these though small in appearance sometimes cause excruciating pain resulting in great disability; (8) the relative position of the foot to the long axis of the leg, when standing, this must be such that strain is avoided; faulty stance must not be neglected; the amount of varus or valgus should be recorded and measures taken to correct either when severe.

If examination of the longitudinal arch reveals depression, a simple carefully fitted support may enable a person to maintain his ambulatory status. The position of the heads of the metatarsals must be observed to detect any possible abnormal relaxation or so-called splay foot. Examination of the toes should include a search for the presence of arthritic changes in the joints, calluses between the toes, bunions, bunionettes and exostoses with overlying bursa. When looking for a short heel cord the examiner should be on the alert in order not to confuse this with a positive Homan sign. The plantar fascia should be palpated for tightness or relaxation and for tenderness to pressure, especially over its attachment to the os calcis, where a spur and overlying bursa may form a so-called policeman's heel. A peculiar gait may disclose the presence of a neurologic lesion of the central nervous system. Correct muscular balance between pronation and supination, control position of the foot. A weak pronated foot may be greatly aided by a laced Oxford or high shoe with a long stiff counter, stiff hank and a thin sole.

The presence of Morton's metatarsalgia or so-called Morton's syndrome may be diagnosed by the characteristic history and observation of localized tenderness on palpation with the finger tip between the third and fourth toes. Relief may be obtained by an operation to remove the edematous nerve.

Rigid flat foot or peroneal spasm may first be treated conservatively which when successful gives a better result than operative correction. Failure of the conservative regimen is usually an indication for simple arthrodesis. ROBERT S. REICH, M.D.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

A Simplification of the Diagnosis of Varicose Veins.

CHARLES A. STROGER and LOUIS H. PALMER. *Ann. Surg.* 1948, 127: 502

The authors individually consider the performance interpretation and relative merit of (1) the Brodie-Trendelenberg test, (2) the comparative tourniquet test of Ochsner and Mahorner, (3) the Perthes test (4) the compression test, and (5) the Schwartz test. They believe that the last three of these tests have little to offer, are unreliable, and reveal no information which cannot be obtained by more accurate methods.

In any case in which a retrograde flow of blood can be demonstrated by the augmented Brodie-Trendelenberg test (as described) irrespective of the status of the deep circulation, not only will no harm be done by ligation, but, actually, the usual benefit to the varicose veins from this treatment should be expected, and even further improvement in the extremity should be obtained by lessening the load carried by the true collateral circulation. Simultaneous ligation of both the superficial and deep venous systems, routinely performed by many with no untoward results, supports this view.

The authors outline in some detail a simplified approach to the accurate diagnosis of varicose veins.

EDWARD H. CAMP, M.D.

Arterial Injuries. MORRIS K. SMITH. *Ann. Surg.* 1947, 125: 566.

The basis for this study consists of 114 wounds of major arteries seen at an evacuation hospital in the European theater of operations together with 4 primary cases in which the patients were operated on in a general hospital in the same theater. In the series there were 4 deaths. Two of the patients had had amputation for gas gangrene, one died with anuria, and the fourth died suddenly the day after operation.

In 43 of the 114 cases seen at the evacuation hospital the type of treatment was not stated. Ligation was performed in 58 cases of which 32 presented gangrene. In 8 cases suture of the lacerated artery was performed with 2 instances of gangrene. Non-suture anastomosis was performed 6 times and in 5 of the cases there was gangrene. The results were compared with reports from other evacuation hospitals and found to be similar.

The author concludes that suture of lateral wounds of the arteries should ordinarily be done, and end-to-end suture should be done in cases in which it is practicable. The use of glass and plastic tubes, or venous grafts to bridge gaps does not seem from the statistics available, to have improved the results yet a consideration of individual cases justifies further trial.

THEODORE B. MAMETZ, M.D.

The Syndrome of Thrombotic Obliteration of the Aortic Bifurcation. RAZEL LAMICK and ARNOLD MORRIS. *Ann. Surg.* 1948, 27: 93.

The authors describe a clinical condition associated with thrombotic obliteration of the terminal portion of the abdominal aorta, and having no relation to the dramatic occurrence of the well known saddle embolism. The thrombotic disease appears to be one of long course and is compatible for years, with a seemingly almost normal life.

Usually the disease occurs in young adults, mostly males, whose presenting symptoms may be one or another of the following: (1) in the male, inability to maintain a stable erection due to insufficient blood flow to the spongy processes; (2) extreme liability to fatigue of both lower limbs; (3) global atrophy of both lower limbs; (4) pallor of the feet and legs.

The clinical findings may be (1) lack of pulsations in vessels below the aortic bifurcation; (2) no oscillations in leg or thigh, but a slight thrill close to Poupert's ligament as determined by an oscillometer; (3) somewhat elevated blood pressure in the upper limb without any renal disturbance; (4) no trophic changes, but wounds of the lower extremity may heal sluggishly or not at all.

The diagnosis is made on the history and physical findings. In selected cases the disease is diagnosed by means of aortography. Prognosis is poor as dry gangrene always occurs after a prolonged period. In most cases, the disease appears first in one iliac artery and progressively involves the terminal aorta and the opposite iliac artery. Extensive periaortitis is a common finding.

The method of treatment is lumbar ganglionectomy or terminal aortectomy with bilateral lumbar ganglionectomy (or both) and the authors present 4 cases to illustrate these methods. In young people whose disturbances are essentially functional without ischemic organic changes, the authors believe a terminal aortectomy with excision of involved iliac segments and bilateral lumbar ganglionectomy is the treatment of choice. In the older age group (patients over 40 years of age) with circulation bordering on ischemia, and with global atrophy, an upper right lumbar ganglionectomy and a left lumbar ganglionectomy to include the first to fourth lumbar vertebrae, if possible, is the recommended procedure. The periaortitis renders resection of the aortic segment too hazardous as a rule. In the "poor cases," (patients close to 60 years of age) presenting an advanced stage of the disease, with frank ischemia or gangrene, the operation is performed in stages with right and left lumbar ganglionectomies, resection of the involved iliac arterial segments, if feasible, and amputations subsequently if necessary.

Surgical treatment is contraindicated in (1) patients seen very late in the course of the disease; (2) in the presence of extensive periaortitis which pre-

SURGERY OF THE BLOOD AND LYMPH SYSTEM

cludes easy aortic resection (3) in patients with fragile extensively sclerotic aortas the ligation of which could not be trusted precluding aortic resection.

EDWARD H CAMP M D

MISCELLANEOUS

Anticoagulants. C. C Burt *Edinburgh M J* 1947
54 632

Anticoagulants were used as therapeutic agents in 61 patients. Heparin was administered either by intermittent intravenous injections or by continuous intravenous drip. A single intravenous injection of heparin acts immediately but the effect passes off rapidly and the clotting time usually returns to normal in about 3 hours. Hence when the intermittent intravenous method is used the clotting time may be normal for perhaps 12 of 24 hours whereas by continuous drip it is possible to maintain the clotting time at any desired level (usually from 12 to 15 minutes). A saline solution containing 10 mgm of the drug per 100 c.c. of solution was regulated to run at about 25 drops per minute. Heparin can be added to glucose plasma, or to whole blood without reaction.

Reports by Swedish workers on the results of treatment of thrombotic disease by the intermittent intravenous administration of heparin are comparable with those of Canadian and American workers using the continuous drip method so that, contrary to what one might expect, the thrombotic process apparently does not spread to any significant extent during the short periods of normal clotting time which occur when the intermittent method is used.

Other workers have shown that the effects of heparin can be prolonged by combining it with a menstruum containing gelatin, dextrose and glacial acetic acid, with or without vasoconstrictor substances. This mixture can be given deeply into the subcutaneous tissue. Single injections containing from 300 to 400 mgm. of heparin result in elevation of the clotting time for about 2 days. Occasionally there is swelling pain and tenderness at the site of injection.

The majority (44 of 61) of the author's patients were treated by the intermittent intravenous injection

method (3 daily doses). After an initial dose of from 50 to 150 mgm. subsequent doses were regulated by according to the response to heparin as measured by the clotting time. A rise to 15 minutes or over was regarded as an adequate response.

The continuous intravenous drip method was used in 8 patients, 7 of whom had operations on the blood vessels. Heparin administration was begun toward the close of the operation or shortly thereafter and continued for periods varying from 15 hours to 12 days. The constant drip was regulated to keep the clotting time to as near 12 minutes as possible.

Dicoumarin which is given by mouth is much simpler to administer than heparin but less easy to control because of the large individual variation in rate and response to it. In this series 300 mgm. were usually given on the first day followed by from 100 to 200 mgm. on the second day. Thereafter the amount was determined by the effect shown on the prothrombin time. Dicoumarin alone was used in 11 patients of the present series and in conjunction with heparin in 6 others. In all cases an attempt was made to keep the prothrombin between 20 and 60 per cent normal. The time taken for the prothrombin time to rise to the required level varied between 40 hours and 7 days after beginning treatment. It returned to normal in from 1 to 7 days. Resistance to combined heparin and dicoumarin therapy was seldom encountered.

If bleeding occurs in a heparinized patient the administration of the drug should be stopped. The use of protamine sulfate which is a specific and immediate antagonist of heparin has been suggested. Blood should be given if necessary. In any case the effect of heparin passes off in 2 or 3 hours. Oozing from the wound and probably some intraperitoneal hemorrhage occurred following operation in one of the heparinized patients and a wound hematoma occurred in another. The prolonged action of dicoumarin makes hemorrhage in a dicoumarinized patient more difficult to control. There is no specific antidote with an immediate action, but Vitamin K in large doses (200 mgm.) has a slow antagonistic action. If hemorrhage is severe repeated transfusions of fresh blood may be necessary.

ORVILLE F. GRIMES, M.D.

excessive local reaction with edema which spread to the larynx and induce respiratory obstruction.

Because of its better localization and greater effectiveness cavernous hemangiomas of the face, scalp and intraoral structures in adults are more satisfactorily treated by means of electrocoagulation than by sclerosing agents. The intensity of the coagulation should be checked by keeping a finger directly over the tip of the electrode and also by observing the surface of the tumor during electrocoagulation. If the color of the mucous membrane changes even slightly from red to gray coagulation should be stopped immediately. The margin of safety between effective electrocoagulation and that which will result in a slough is very narrow and can be determined only by experience.

During the coagulation the electrode should be kept as far as possible from Stensen's duct, the muscles of mastication, the motor nerves, and other important structures. It is especially important that ample clearance be given the branches of the facial nerve. Spasm of the facial muscles often will occur during intensive electrocoagulation even when the tip of the electrode is 1 cm. or more from a branch of the facial nerve. This may result from direct stimulation of the muscle or from transmission of the current to the nerve by the intervening tissues. Accidentally active contraction of the facial muscles is not necessarily an indication of impending injury to the seventh nerve.

Pleniform or racemose hemangiomas are more difficult to obliterate than simple cavernous angiomas because of the increased pressure within the component blood vessels resulting from the arteriovenous communications. When seen early in life interstitial radiation may control them but ligation of the afferent vessels frequently is also necessary. In adults, lesions of this type with only a slight impulse often can be shrunk by means of electrocoagulation while radiation or injection of sclerosing agents alone is not likely to be of benefit. If the lesion is not too extensive, excision may be feasible and at times is the most effective means of control. This frequently is the case also when the expansive force is pronounced.

In cases in which phleboliths in hemangiomas about the face cause discomfort removal of the offending calculi is indicated.

A Modification of the Waugh-Ruddick Test for Increased Coagulability of the Blood and Its Application to the Study of Postoperative Cases. *SEYMOUR B. SILVERMAN, Blood 1948 3 147*

A modification of the Waugh-Ruddick test for increased coagulability of the blood is presented wherein recalcified plasma is used instead of whole blood. This technique gives a sharper endpoint, keeps the reaction volume constant, has a reaction time which is not too extended and still retains the advantages of the Waugh-Ruddick test.

This new technique was used to study the effect of operation on the coagulability of the blood and

tests were performed on 9 patients admitted to the Royal Victoria Hospital, Montreal, for operation. All operations were done under spinal anesthesia. Tests were done preoperatively and postoperatively. The results indicate that there is a definite increased coagulability of the blood which begins within 24 hours after operation and may last for a week or more. In all cases the coagulation time was normal at the end of 3 weeks.

Since thromboplastin initiates and determines the speed of coagulation, the decreased coagulation time after operation can be explained by increase in the amount of available thromboplastin obtained from either the platelets or the tissue juices. Since the postoperative thrombocytosis does not occur until the sixth or seventh day, the increased circulating thromboplastin is presumably derived from damaged tissue in the operative area.

ROBERT MAYO TERRY, M.D.

ANTISEPTIC SURGERY TREATMENT OF WOUNDS AND INFECTIONS

Local Treatment of the Whole Thickness Burn Surface. *HARVEY S. ALLEN, Surg Clin N America 1948 28 125*

It is neither possible nor logical to dissociate the problem of general care of the burned patient from care of the local burn wound. After the burn shock has been successfully combated it should be anticipated that the patient will exhibit a serious secondary anemia and that a nitrogen imbalance will occur. Beginning the third or fourth day after the injury, and every second day thereafter, the patient's blood should be checked to determine the hematocrit, hemoglobin and plasma protein levels. These few blood examinations are sufficient to indicate the patient's general condition provided there is an adequate urinary output. Any significant lowering of these blood values must be corrected to keep them at a high normal level. A daily diet high in vitamin content, and containing 2 to 3 gm. of protein per kilogram of body weight must be given. On about the fourth day the patient with a severe whole thickness burn will exhibit a steadily progressive secondary anemia and loss of protein which must be corrected otherwise wound healing is interfered with and weight loss becomes extreme. The patient's progress must be constantly anticipated, checked and treated until the wound is closed by grafting.

The objective in treating severe burns has been to obtain closure of the whole thickness skin loss within a period of 3 weeks following the burn. The dressing applied at the time of the initial local burn is not disturbed for 10 days unless there are definite signs of infection. On the tenth day the patient is taken to the dressing room where the entire wound is visualized and an accurate estimate of the degree of the burn is obtained. By this time the patient's general condition is well stabilized, the demarcation between incomplete and whole thickness skin loss is apparent and incomplete whole thickness burns are entirely

healed or will be in another 2 or 3 days. The extent of the area of whole thickness burns can be readily determined as if there is a defect larger than a silver dollar wound closure is proceeded with as soon as possible.

Several methods are available for the removal of full thickness burn slough. Usually the most suitable method is that of daily dressing at which time the loose portions of the slough may be cut away by the scalpel and the raw area covered by fine mesh gauze, fresh Dakin's solution and a pressure dressing. This method is time-consuming and painful to the patient.

The second method for the removal of burn slough is the application of pyruvic acid in situ. This method has proved to be efficient for rather circumscribed perforations. The 1 per cent pyruvic acid is applied on the tenth day and excised daily thereafter. Repeated dressings are necessary and the application immediately after the application of pyruvic acid is important. The advantage of this second method is that of quick separation of the more superficial types of full thickness burns. With this method the areas are ready for grafting in 10 to 15 days following the burn.

The third method of treatment is that of surgical excision. At the present time this is the preferred method for serious burns. The burn is examined on the tenth day and the area of whole thickness destruction is noted. In cases in which the area is larger than 2 inches in diameter surgical excision is done in the operating room under a light general anesthetic. The whole thickness skin slough is surgically excised with bleeding to be controlled by the use of the electrocautery. The surgeon takes care to attain the exact line of cleavage between the burn slough and the underlying tissues. All bleeding is controlled by the use of pressure and at the completion of operation the wound is dressed with dry fine mesh gauze and occlusive pressure dressings. Following excision the wound is not disturbed for 3 to 4 days when the patient is returned to the operating room where the clean surface is covered with split thickness skin graft. This method is efficient in that the wound is dressed a minimal number of times prior to grafting

and spares the patient much pain. This method is not useful on burns of the face or neck because of the normally rapid separation of slough.

Primary surgical excision has not seemed to be feasible because it is difficult to estimate correctly the depth of a burn on the initial inspection.

FRANK F. KENTON, M.D.

ANESTHESIA

Diaphragmatic Paralysis. W. H. CAVALLI and LUNA A. GIFFORD. *Anesthesiology* 1945, 9: 45.

Anesthesiologists are accustomed to thinking of diaphragmatic paralysis as full for intercostal paralysis in deepening stages of anesthesia. Diaphragmatic paralysis in the presence of functioning intercostal muscles is recognized by the observation of depression of the upper abdomen on inspiration with slight elevation of the abdomen on expiration. This is the converse of the rocking chest respiration seen in profound intercostal paralysis.

The incidence of diaphragmatic paralysis was 1 in 1,000 in the series of 18,000 anesthetic cases reviewed by these authors.

Several examinations were presented to illustrate that diaphragmatic paralysis may precede intercostal paralysis in many instances.

Illustrative examples showed that:

1. The phenomenon can recur in the same patient on different occasions when different gaseous agents are used.

2. Diaphragmatic paralysis may occur in second plane or the third stage of anesthesia, or in deeper planes.

3. Diaphragmatic paralysis may persist as long as 15 days before recovery.

4. Paralysis could have its onset several hours after termination of the anesthesia.

5. Paralysis can occur when local anesthesia is used.

Diaphragmatic paralysis has been observed during the use of nitrous oxide, ether, cyclopropane, sodium pentothal, avertin and procaine. No etiology was suggested by analysis of the findings in the cases observed.

MAX K. F. M.D.

PHYSICO-CHEMICAL METHODS IN SURGERY

ROENTGENOLOGY

Clinical and Roentgenologic Evaluation of Venography
EDGAR C. BAKER. *Am. J. Roentg.*, 1947
58, 603.

The author's technique is as follows. Diodrast is used as the contrast media. A tourniquet is applied only to facilitate venipuncture; it is then released except in the occasional case in which no previous examination only the internal saphenous vein was visualized with evidence of deep obstruction yet with absence of other findings of block. In these cases the tourniquet, left in place may show a highly incompetent deep circulation but no evidence of block. Venipuncture is made with the use of a 25/26 gauge needle in any available vein below the ankle. Twenty cubic centimeters of dye is injected over a period of 3 minutes if the leg appears normal, if the vessels are suspected of being abnormal, the injection is prolonged. Three 14 by 17 inch films are used. Stereoscopic pairs are made on a single film and the area covered extends from the ankle in the lower pelvis. The first exposure is made after about 8 c.c. of dye have been injected (45 to 60 seconds) and the injection is continued slowly while the remaining films are exposed. The last exposure and completion of the injection approximately coincides.

Most of the dye enters the deep circulation fairly close to the ankle through deep communication veins. A smaller quantity spreads superficially to demonstrate the external veins about the knee. Usually the greater saphenous is well visualized. Normal subjects, remaining motionless in the supine position frequently show dye in the deep and superficial veins from 5 to 20 minutes after the injection. Movement of the foot or leg however quickly empties these veins.

Acute superficial block. The dye enters the deep circulation promptly. Some of the dye passing into the superficial circulation stops abruptly at the site of a connecting vessel turning directly inward or backward to enter the deep circulation or to other parts of the superficial plexus. No superficial veins are demonstrated beyond this block. Occasionally a different pattern is observed: short straight nondilated and nondilated veins extend upward and fade out in the peripheral tissue. Recognition is difficult without repeated studies. Acute superficial block is frequently confused with chronic superficial and chronic deep block.

Chronic superficial block. The veins are dilated and tortuous; numerous large superficial veins are visualized but not opacified; the deep veins show some dilatation and tortuosity; upward passage in the deep veins is slow; small connecting veins extend inward toward the deeper circulation; the ahmpnt turning toward the deeper circulation as in the acute form is also seen.

Acute deep block. Acute superficial block is always present; the deep veins in the involved area are rarely visualized; occasionally a thrombosed vein is demonstrated either in the superficial or deep circulation.

Chronic deep block. There is partial or complete absence of the deep circulation; the internal saphenous is visualized completely and is dilated and tortuous; short lengths of communicating veins (usually large and tortuous) extend from the saphenous vein to fade out into the soft tissue; if the deep block is limited to the foreleg most of the dye will enter the deep system above the knee.

Thrombi may be demonstrated as a mass within the vein by partial obliteration of the vein for a variable distance which shows a ragged border along the side of the thrombus and by complete block.

The results have been satisfactory in from 88 to 90 per cent of the cases.

The author concludes from his analysis of these cases that all disease processes involving the leg veins originate in the superficial system since the superficial veins are frequently involved separately while disease of the deeper system is always accompanied by superficial involvement. Thus it is no longer necessary to assume the occurrence of damage to the intima of the deep vessels to account for the presence of thrombosis of the deep circulation. Post operative thrombosis of the deep veins is due to trauma of the superficial vessels and the superimposed venostasis caused by prolonged bed rest.

ROBERT DUBINS LARSEN, M.D.

The Possibilities and Limitations of the Roentgenologic Examination of the Soft Tissues (Possibilités et limites de l'examen radiologique des tissus mous) GONROETTE J. MELOT. *Brussels méd.* 1948 28 67.

By means of roentgenologic technique it is possible to render visible the course of the blood vessels and nerves, to outline the muscular planes particularly for the purpose of localizing foreign bodies, to locate neoplasms with reference to the surrounding tissues and to demonstrate articular pathology before typical bone changes have developed.

The author made a study of the differing contrasts obtainable with media of absorptive capacity for the roentgen rays; this capacity somewhat approached that of normal or pathologic tissue but he considered the data so far obtained of too specialized a character for presentation at this time. He is content to present a few representative findings helpful in the diagnosis or treatment of medical and surgical conditions. Roentgenographs are demonstrated which show that sebaceous cysts of the skin and even benign tumors can be distinguished from malignant infiltrating new growths. In the work on the female breast inflammatory processes are differentiated from tumors and the difference between benign

tumors and malignant infiltration was readily recognized. The amount and dispersion of the infiltrating process was often shown to be much greater than was suspected clinically which provided indications for and delimited future operative procedures.

Disadvantages of the method are the frequent difficulties encountered in the interpretation of the roentgenograms obtained. Chronic inflammatory changes, especially in the breast, may render a certain diagnosis extremely difficult or impossible. Another factor producing disturbing shadows and distortions in the female breast tissues is the habit of implanting radium seeds for the treatment of benign tumors or even Reclus disease, these shadows and distortions very closely resembling the picture proffered by malignancy. These shadows may mask the presence of a tumor. Even the folds of skin in the senile breast may prove confusing.

However taking into account the disadvantages here enumerated, and while awaiting a sufficient study and practice to enable the roentgenologist to properly discount them the author still insists that roentgenologic examination of the mammary gland gives more reliable information than clinical examination. Roentgenologic examination is equal to dissection of the gland itself, and equivalent to a macroscopic examination of the dissected specimen. It is the interpretation of these findings which must be made with considerable prudence.

JOHN W. BRENNAN, M.D.

Roentgenologic Aspect of Certain Lesions of Bones: Neoplastic or Infectious? JOHN R. HODGSON, DAVID G. POOR, and H. HERMAN. *Osseous Radiology*, 1944, 50: 65.

The term neurotrophic is used to describe changes in the soft tissue and bone presumed to be the result of disturbances in the nerve supply to that part. In the past, certain lesions of the bone, especially in the feet, have been ascribed to "neurotrophic" disturbances. The purpose of the article was to investigate the validity of the assumption that these changes in bone were due to "neurotrophic" disturbance.

Sixty-one cases were reviewed. Of the 61 patients, only 15 were found to have diseases involving the nervous system. In the cases in which lesions of the nervous system were present there seemed to be no evidence indicating that the neurotrophic changes were the direct cause of lesions of the bone. The lesions of the bone were the result of chronic osteomyelitis secondary to infection of soft tissue contiguous to the bone.

The authors concluded that similar lesions of the bones of the feet may be produced by a wide variety of systemic and local diseases. The changes in the bones of the feet may be due to a type of osteomyelitis secondary to chronic infection of the soft tissue contiguous to the involved bone. Review of the 61 cases in which the roentgenograms of the feet presented evidence of "neurotrophic change" revealed that in every case there was infection of the contiguous soft tissue.

The authors believe that the assumption that these changes in the bones of the feet are due to neurotrophic disturbance is invalid.

Pulmonary Disease in Workers Exposed to Beryllium Compounds: Its Roentgen Characteristics. LUCIEN M. PASOUCCI. *Radiology*, 1944, 50: 3.

Certain pulmonary changes occur in people who have been exposed to the dust of beryllium compounds. These changes, although similar in many respects to those observed in certain recognized disease entities, are thought to be of sufficient difference to warrant their separate classification. The roentgenographic appearance of pulmonary changes is usually delayed for an average period of 24 months. Dyspnea, cough, and weight loss are the most frequent symptoms. Cyanosis is sometimes observed, there is no involvement of the peripheral nodes, and no constant enlargement of the liver or spleen.

Four patients had complete laboratory work-ups. All had polycythemia and the blood alkaline phosphatase was elevated in 3 patients. Ventilatory function tests confirmed the respiratory disability and established the secondary nature of the polycythemia. Other tests, including that for tubercle bacilli, were negative. Roentgen examination of the skeletal system revealed no abnormalities. Less than 100 per cent of the 30 patients were followed. Of these, 30 per cent had died, 30 per cent were unimproved, and 40 per cent were improved. The predominant pathological finding was a granulomatous reaction infiltrating or completely obliterating the interstitial tissue. These masses contained dense hyaline material and infiltrates of lymphocytes, plasma cells, and macrophages. Many multinucleated giant cells with or without inclusive bodies were present. The mediastinal nodes may show a similar reaction.

Radiographically the pulmonary process was well developed in all of the author's cases and consisted of widespread fine-to-punctate, and coarsely nodular infiltration which involved both lungs uniformly. The apices and costophrenic sulci were generally clear. These lesions were of two types: granular and nodular. The former are more prone to become confluent. The nodular lesions vary little in size on the single film and measure up to 5 mm. in diameter. They are less numerous but are symmetrical in location. The vascular markings are obscured, and there may be mediastinal widening and cardiac enlargement.

In some of the patients, the lesions progressed slowly while in others no change was apparent in a 2 to 3 year period. Rarely complete clearing occurs; the more common finding is clearing with fine nodular residues. Partial or complete clinical remissions have occurred with little roentgen change, and well advanced pulmonary lesions may be demonstrated in workers without symptoms.

The nodular and confluent lesions are thought to be more serious. However, further study and a longer period of observation is required for any but a

guarded prognosis. Pneumoconiosis, Boeck's nodular chemical pneumonitis, tuberculosis, tuberculous bronchomycoses, cardiovascular disease, erythema nodosum must be differentiated. ROBERT BURTON LEWIS, M.D.

Observations on Diffuse Pulmonary Lesions. HENRY FEISOW and G W HEUBELIN *Am. J. Roent.*, 1948 59 59.

The authors describe their clinical and roentgen experience with diffuse pulmonary lesions during the 3 years at Percy Jones General Hospital, Bat Creek, Michigan by including specially selected from civilian practice. The difficulties in arriving at a proper diagnosis often have been impressed.

It was found that it is hazardous to express an opinion on the basis of a single roentgen study. Even multiple examinations made at certain intervals may not be absolutely diagnostic. A co-ordination of the roentgen findings with clinical studies is apt to lead to the best results. In some few instances postmortem examination may have to furnish the final proof.

The authors found the following classification of distinct aid in evaluating the various types of diffuse pulmonary lesions (the types most likely to cause pulmonary densities are in italics).

1 Cystic lesions (a) *congenital cystic disease* (b) pulmonary pneumatocele and (c) neurocutaneous syndromes (*tuberous sclerosis*).

2 Aspiration (a) hemorrhage (b) drowning, (c) *lipoid pneumonia* (d) changes secondary to achalasia or esophageal malignancy and (e) foreign bodies.

3 Inhalation-pulmonary edema A (a) acetylene (b) beryllium, (c) carbon tetrachloride, (d) kerosene (e) nitric acid and (f) phosgene B dust-pneumoconiosis (a) *anthracosis* (coal dust), (b) *bagassosis* (bagasse) (c) *barilosis* (barryta) (d) *byssinosis* (cotton lint) (e) *graphite* (carbon) (f) *siderosis* (iron) (g) *silicosis* (silica) including *chalcosis* (potter's disease) and *calcosis* (marble-cutter's disease) and (h) *silicatosis* (asbestosis) C lipidol and D other mal.

4 Deposition (a) *xanthomatosis* and (b) *hemoidrosis*, *mitral stenosis*.

5 Embolization (a) fat embolism (b) multiple infarcts (septic or aseptic) and (c) annular shadows due to bronchial artery occlusion.

6 Trauma (a) blast and (b) pulmonary collapse complicating fractures of the skull.

7 Vascular (a) *chronic passive congestion* (b) *pulmonary edema* and (c) pulmonary congestive changes due to nephritis (nephritic butterfly).

8 Bronchial (a) *electrasis* (b) *bronchiectasis* (c) *chronic bronchitis* and (d) bronchial changes with cystic disease of the pancreas.

9 Infectious A bacterial (a) *pyemia* (b) *broncho-pneumonia* (c) *brucellosis* (d) *leishmaniasis* (e) *tuberculosis*, (f) *syphilis*, (congenital) (g) *fusospirochetal* and (h) *glanders* B viral (a) atypical pneumonia *psittacosis* C, *mycoses* (a) *actinomycosis* (b) *aspergilliosis* (c) *blastomycosis* (d) *coccidioidomycosis* (e) *histoplasmosis* (f) *monilliasis* (g) *torulosis* and (b)

toxoplasmosis and D others (a) tropical *paragonimiasis*, *schistosomiasis* (b) pulmonary alveolar *adenomatosis*, and (c) *amebiasis*, *ascariasis*, and *echinococcosis*.

10 Allergic (a) tropical eosinophilia (b) Loeffler's pneumonia (c) *periarthritis nodosum* and (d) *disseminated lupus*.

11 Fibrotic (a) acute diffuse interstitial fibrosis (b) *scleroderma* (c) irradiation fibrosis (d) *bronchiolitis obliterans* and (e) pulmonary changes in drug addiction.

12 Hemopoietic (a) *polycythemia vera* (b) sickle cell anemia, and (c) *leucemia*.

13 Boeck's sarcoid.

14 Malignancy (a) lymphogenous and hematogenous metastatic malignancy (1) *sarcoma* (2) *carcinoma* (b) lymphomatous disorders (1) *Hodgkin's disease* (2) *lymphosarcoma*.

15 Calcific (a) hyperparathyroidism vitamin D poisoning (b) *mycoses aspergilliosis* *histoplasmosis* (c) *mitral stenosis* (d) *miliary tuberculosis* (e) metastatic osteogenic sarcoma with bone production and (f) *arteriosclerosis*.

In interpreting the roentgenograms certain aspects are of more or less value from the point of view of differential diagnosis. These are (1) the size and number of lesions (2) the appearance, (3) the distribution (4) the progression and retrogression and (5) the presence or absence of an associated mediastinal enlargement and increased prominence of the hilar shadows.

Brief resumes are given of 18 interesting cases and their respective roentgenograms are presented to illustrate the point in question.

An extensive bibliography is appended.

T LUCUTIA, M.D.

Postbulbar Ulcer of the Duodenum. ROBERT P BALL, ALLAN L. SEGAL, and ROSA GOLDEN *Am. J. Roent.*, 1948, 59 90.

Duodenal ulcer located distal to the bulb is rather uncommon. Because of the high incidence of hemorrhage especially of the massive type which occurs in the condition it is important that diagnosis be made with accuracy. Unfortunately, the standard procedures do not always lead to the best results.

The authors review in detail the available literature. The incidence of postbulbar ulcer of the duodenum is undetermined. In routine autopsy material the condition is found in from 5 to 20 per cent of cases with duodenal ulcer. Surgical statistics indicate a somewhat higher incidence, whereas the roentgenologic reports for obvious reasons give much lower values.

Anatomically and roentgenologically the duodenum is divided into the pars superior, the descending limb, the pars inferior, and the ascending limb. The terms "first portion," "bulb," "cap," and "pars superior" are used synonymously although the bulb is a subdivision of the pars superior representing about five-eighths of its length. The distal extremity of the pars superior is the flexure, the genu

superius. Any ulcer located distal to the apex of the bulb is classified as a postbulbar ulcer. Since in the presence of inflammation it often becomes impossible to determine accurately the apex of the bulb, the cases reported are ulcer craters located in or distal to the genu superius (flexure), in the proximal portion of the descending limb of the duodenum.

The use of an exaggerated oblique projection with the patient in horizontal position or with the head lowered below the horizontal plane is necessary to demonstrate postbulbar ulcer roentgenologically. The anatomic variation of the pars superior and the amount of irritability incident to the ulcer determine the degree of rotation required in the positioning of the patient. According to Schons, the position must be so chosen as to yield the most satisfactory lengthening out of the upper duodenum. Spot films with controlled compression are of additional value.

The most important roentgen sign of postbulbar ulcer is a smooth rounded indentation of the wall of the duodenum at the level of the crater with an eccentric narrowing. Occasionally more than one indentation is noted opposite the crater. Enlarged, distorted mucosal folds, irritability of the bulb and hypermotility are associated findings. The authors observed no mechanical obstruction in their series.

The differential diagnosis includes duodenitis, diverticula and neoplasms of the duodenum. The various distinguishing features are discussed.

The article is illustrated with roentgenograms showing the anatomic variations of the normal duodenum and the characteristic signs in 6 cases of postbulbar ulcers.

T. LEUCOMA, M.D.

Hilar Densities Simulating Neoplasms. CHARLES GOTTILF and HERBERT S. SZARLEK. *Radiology* 94:5 50: 57.

The roentgen appearance of hilar densities is rarely if ever specific for any one disease entity. Eight cases presenting bronchogenic carcinoma, pulmonary tuberculosis, atypical pneumonia, central pneumonia, eosinophilic pneumonia, lung abscess and pneumonia with delayed resolution are reported. Due to the similar roentgenographic appearance of all these lesions, the authors emphasize the importance of utilizing all possible diagnostic aids, such as bronchoscopy, laboratory procedures, history and serial radiograms before a final diagnosis is attempted.

ROBERT BURKE LEWIS, M.D.

The Role of the Roentgenologist in the Diagnosis of Polypoid Disease of the Colon. PAUL C. SWENSON and RUSSELL W. ORR. *Am. J. Roentg.* 94:5 50: 65.

The authors evaluate the methods and techniques that can be used in the diagnosis of polypoid lesions of the colon. They also discuss the responsibility of the roentgenologist as a consultant to the internist or surgeon and as a clinician to the patient.

Methods and criteria of diagnosis. Obviously a proper preparation of the patient is necessary. The various methods of examination include the single

contrast study, the double contrast study (with stereoscopy) and the roentgenoscopically controlled compression study. The first roentgenologic clue to the presence of a polypoid lesion comes during the initial filling of the colon with the barium sulfate water suspension. An evanescent concave border is the advancing opaque column or a filling defect is seen. Spot pressure films bring out the defect posteriorly. If the tumor is pedunculated the point of origin of the pedicle may also be visualized. Since polypoid lesions often are multiple the entire extent of the colon must be carefully scrutinized. The patient is re-examined roentgenoscopically after the evacuation of the enema. Whenever the findings are inconclusive the double contrast study is used.

Puckering of the bowel wall at the site of attachment of the polypoid growth is pathognomonic.

Responsibility to the surgeon or internist. Formerly the authors were of the opinion that at least two examinations are necessary before surgery is advised. Now they think that a second examination is in order only when neither a pedicle nor bowel dimpling can be demonstrated. A visualization of the point of origin of the pedicle will greatly aid the surgeon in operating the bowel at the exact site.

Responsibility to the patient. In reporting the findings the term "polypoid lesion" is preferred to the term of "polyp" because the latter may give a false impression of benignancy. Neither the pedunculated nature of the tumor nor its size constitute criteria of possible histopathologic evaluation.

Patients with polypoid lesions should be restaged postoperatively at frequent intervals regardless of the histopathology of the surgical specimen. At least 30 per cent of the combined total of polypoid tumors of both rectum and colon are found beyond a sigmoidoscopic reach of 20 inches.

Case reports. Patients with polypoid disease seem to fall into four different clinical groups. Group 1: hemorrhage, negative sigmoidoscopic examination. Group 2: hemorrhage with a proved growth in the rectum or rectosigmoid, clinically group 3: hemorrhage or nonspecific complaints, no sigmoidoscopic studies, and group 4: complaint is consistent with ulcerative colitis. The authors present brief histories in typical cases of all these groups (7 cases altogether) and use the respective roentgenograms for the illustration of the salient points. Four classes of polypoid disease of the colon are distinguished: (1) single lesion, (2) limited but multiple lesions, (3) true multiple polyposis, and (4) polypoid manifestations in ulcerative colitis.

In conclusion the need for careful and repeated study of the colon is emphasized in cases of obscure bleeding.

T. LEUCOMA, M.D.

The Treatment of Breast Cancer by Radium and Roentgen Therapy (Le traitement du cancer du sein par C. thérapie et roentgénéthérapie). J. MAXIM. *Acta radiol. Stockh.*, 94:7 53: 593.

The author, Director of the Cancer Institute of Louvain, states that because of its surgical access-

lity and the possibility of radical surgery breast cancer has always been attacked by operative measures. These in his opinion leave much to be desired the eventual outcome. Therefore in a series of patients he has attempted a special technique of irradiation therapy, and he compares the results of irradiation alone of irradiation with hormonal therapy and of preoperative surgical irradiation. The Steinthal classification was employed the first two groups being considered operable cases and the last two inoperable. These statistics have been carefully evaluated and studied objectively.

Biopsy was taken only after preliminary irradiation with from 500 to 750 roentgen units to the area of biopsy. If the tumor was small it was removed or biopsy with the electrosurgical cutting current. If it was large an aspiration biopsy was performed. If the biopsy was positive, the entire area which would have been removed by a surgical procedure was seeded with radium elements. In the area of the tumor the needles of radium were placed 1 cm. apart. In the axilla and in the more distant areas from the tumor the needles were placed from 2 to 3 cm. apart. The needles contained 1 mgr. of radium with $1\frac{1}{2}$ cm. of radiating surface and $\frac{1}{8}$ mm. of platinum filtration. A total of from 100 to 120 mgr. of radium were employed and left in place for from 5 to 7 days. This was followed either by 1,000 to 1,500 roentgen units of irradiation to the breast and a similar amount to the axilla and sometimes to the supraclavicular area or by similar irradiation with a 6 to 12 gr. radium bomb.

The considerable radiation dermatitis which followed was treated with penicillin and vitamin A ointment. The skin in most cases became soft and supple, but some cases presented the typical post-radiation lesions.

Before 1931 200 operable patients had been treated in this manner. Of this group treated over 5 years, 116 (53.6%) were alive and well at the end of 5 years and of 125 who were followed up for 10 years 45 (36%) were alive at the end of 10 years. The inoperable patients who had supraclavicular metastases or distant metastases were usually given palliative treatment. No therapy was given to patients with liver metastases. Sedative radiation was given for pain in small doses of from 25 to 50 roentgen units per sitting for total dosages of from 500 to 750 roentgen units. The 5 year survival rate for this series was only 4.5 per cent.

The author compares these series with one in which surgery and irradiation was used. The percentage of 5 year survivals was approximately the same as when irradiation alone was used. When hormone therapy was added in the form of castration there appeared to be no very great difference in the survival rate. In individual cases especially those with osteoclastic metastases or large ulceration certain surprisingly beneficial results were obtained from the use of subcutaneously implanted stilbestrol. The pain of osseous metastases seemed to be diminished in many instances by the use of testosterone

Statistical results of hormonal therapy were not included. The author also mentioned the beneficial results of irradiation in recurrences and metastases following radical mastectomy.

The author concludes by stating that irradiation therapy has certain advantages over surgical therapy not the least of which is the preservation of the skin. He believes that the radiation dermatitis which accompanies this mode of treatment is a minor inconvenience. This treatment however is not simple and requires rather large dosages of radium.

WILLIAM C. BECK, M.D.

Carcinoma of the Cervix. A Discussion on the Value and Techniques of Supplementary X Ray Therapy. J. G. WINTERBURN. *Brit J Radiol* 1948 21: 27

The author discusses the value of combining radium and roentgen therapy in the treatment of carcinoma of the cervix. The procedure described is a modification and development of that which has been used at the Royal Cancer Hospital for some years. Roentgen therapy supplementary to radium is given with the object of delivering an effective dose to the lateral portions of the parametria and to the lateral wall of the pelvis. It is felt that the region close to the uterine cervix is adequately irradiated by the intracavitary radium. The irradiation is confined to rather narrow (15 by 4-6 cm.) fields lateral to the area which has received at least 6,600 roentgens from the radium application. It is directed toward 4 principal areas of lymph node metastasis including the internal iliac, the external iliac, the obturator and the parametrial lymph nodes.

The very ingenious apparatus used for the accurate localization of the cervix to the position in which the treatment is to be given is described with illustrations of the intravaginal and external components and the measuring devices that allow for the correction of the distortion. The pelvic tripod which is a simple but effective means of obtaining and maintaining accurate positioning in the prone position is described and illustrated. A very complete description of a device called the pelvic measuring bridge for estimation of the dose distribution to the critical areas is included. By the use of this instrument it is possible to reconstruct the treatment conditions in space and to accurately determine the depth doses by the use of isodose charts. The external fields that may be used are two anterior abdominal two sacral two gluteal and two sciatic fields. Compression is used if possible, to decrease the distance factors. At present irradiation is being given at 400 kilovolts. The author believes that when higher voltages are available the treatment will be simplified by allowing the administration of adequate dosages through fewer fields and that this would also even further increase the accuracy. Obese patients are not accepted for external therapy but with higher voltages this may become possible.

The method described is rather elaborate due to the numerous mechanical devices but in actual use

It has been found that the use of these devices makes for simplicity in setting up the patients, the accuracy of aim is increased, it is possible to restrict the size of the fields to fix the conditions, in that they can be adequately reproduced at each treatment, and to give adequate data for accurate estimation of the dose distribution.

S. A. PATTERSON M.D.

RADIUM

Dosage Estimation and Distribution in the Radium Treatment of Carcinoma of the Cervix Uteri.
M. LEDERMAN and L. F. LAMERTON *Brit J Radiol.* 948

Radium dosage, although effective clinically, has always been empirical. The dosage is expressed in milligram hours or in millicuries destroyed. Methods had been devised in an effort to simplify the distribution of a given dose of radium; these however were so cumbersome that it was considered impracticable to consider the use of radium as a routine.

The authors present their method of estimating the dose of radium at any given point in the pelvis. The procedure may be used routinely and takes into account individual variations in anatomy.

A double exposure film of the pelvis is taken, with utilization of a tube shift from which the positions of the radium sources in the pelvis can be determined. A contour projector is used to determine the necessary dosage at any given point in the pelvis. From the clinical point of view it is possible, with this method, to estimate the dosage received by the diseased tissue and adjacent normal structures, to investigate the anatomical and technical factors affecting dose, and the correlation of radium and external radiation therapy.

Radioactive Sodium as a Tool in Medical Research.
EUGENE H. QUINBY *Am J Roentg* 947 35, 741

This is a condensed account of some uses of radioactive sodium 24 as a tool in medical research. The information is collected partly from the literature and partly from the author's personal experience.

Radioactive sodium can be produced by bombarding sodium with neutrons or deuterons, magnesium with neutrons or deuterons, or aluminum with neutrons, according to the five following formulas:

In every case the product is sodium having atomic weight 24 instead of 23, which disintegrates by the ejection of a beta ray, transforming the nucleus to magnesium and emitting gamma rays as the magnesium becomes stabilized. The half-life is 15 hours.

The radioactive sodium, whether originating from a cyclotron or the uranium pile, is usually delivered for use in the form of a solution of sodium chloride, which, however, contains only an extremely small fraction of the radioactive atoms.

In animal tissue the sodium is uniformly distributed throughout extracellular body fluids, freely passing back and forth across capillary membranes. When radioactive sodium is administered by mouth or intravenously a similar distribution occurs. Its presence can be detected by the Geiger-Mueller counter.

One of the first applications of radioactive sodium concerned the determination of the volume of the extracellular fluid of the body. This work was carried out by Kallreiter and his associates at the University of Rochester by using radioactive sodium and thiocyanate simultaneously. The results obtained with sodium gave about 31 per cent of body weight as "sodium space" extracellular fluid, of which 15 per cent was plasma and 85 per cent, interstitial fluid. The thiocyanate results indicated a "thiocyanate space" representing 33.5 per cent of the body weight.

As a sequence of these investigations, Fox and Keston of Columbia University, New York, studied the mechanism of shock produced by burns and trauma. From previous clinical observations it appeared that in extensive burns a redistribution of sodium and potassium takes place and that the "antiosodium barrier" between extracellular and intracellular fluids might break down. By determining the "sodium space" with radioactive sodium, Fox and Keston found in experimental animals that the burned tissues (skin and muscle, which normally contain very little sodium) indeed take up a large proportion of the administered isotope. Such animals treated by intraperitoneal injection of normal saline solution equal to 16 per cent of their body weight recovered, while similarly burned animals which were left untreated invariably died. Later, some very successful results were obtained also in human beings by the administration of large volumes of isotonic (sixth molar) sodium lactate solution by mouth or infusion.

A somewhat similar work was done by Greenspan and his associates at the University of California, San Francisco. These investigators studied with the aid of the radioactive sodium and other radiotopes the mode and rate of formation of the cerebrospinal fluid and especially the role of the barrier membranes in separating the blood plasma and cerebrospinal fluid. The conclusions were reached that the exchange between the blood and the brain takes place by a process of secretion and not by simple diffusion or ultrafiltration.

PHYSICO-CHEMICAL METHODS IN SURGERY

The author herself studied *in extenso* the variation of the circulation time in peripheral vascular disease. Sodium was injected into an antecubital vein with the window of the portable shielded Geiger counter against the sole of the foot, and the arm to the circulation time was measured. The work led to the development of a very valuable clinical test.

It was found that it takes a certain time before an equilibrium of radiosodium concentration is built up between plasma and extracellular fluid and that the shape of the curve expressing the corresponding increase of the counting rate often can be correlated with the clinical condition of the vessels. Such radiosodium 'build up curves' have been found useful in diagnosis, prognosis and the selection of therapy in arteriosclerosis, hypertension, thromboangitis obliterans, Raynaud's disease, various thrombi, emboli, trench and immersion foot, and frostbite.

Other problems that have been studied by the author and her associates with the aid of radioactive sodium as tracer include testing of the value of various drugs and physical therapy procedures in the treatment of peripheral vascular disease, testing of the efficiency of various tourniquets to cut off circulation, investigation of mechanical methods of artificial respiration to determine whether blood could be made to circulate by a respirator if coagulation had not occurred, and more recently determination of the most efficient method for the administration of penicillin by means of a nebulizer in certain pulmonary conditions.

In concluding the author emphasizes that in all such experiments the amount of the radioactive tracers given must be small so as not to constitute a danger to the patient. On the basis of Marwell's formula, it is safe to use tracer doses of from 2 or 3 microcuries of radioactive sodium per kilogram of body weight and to repeat them a few times at reasonable intervals. This dosage, however, does not apply to any other radioactive isotope.

Comparison of the Lethal Effect of Neutrons and Gamma Rays on Mouse Tumors by (a) Irradiation of Grafted Tumors in Vivo (b) Irradiation of Tumor Fragments in Vitro L. H. GRAY and JOHN READ *Brit J Radiol.*, 1948, 21 5

Carcinoma 2146 was inoculated into the thigh of a mixed strain of mice. When the tumor reached the size of 10 mm³ the mice were irradiated with a neutron beam (2.8 MEV) or gamma rays (500 mgm. radium plaque).

The lethal effect of both x irradiation and neutrons as determined experimentally on the broad bean root was due to chromosome and chromatin changes. The efficiency of neutrons in rendering tumor growth nonviable increases with decreasing neutron energy (slow neutrons).

The mean lethal dose in vivo and in vitro of neutrons and x irradiation (efficiency factor) was 24 and 9.5 times less respectively.

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Blood and Liver Proteins in Surgical Patients as Related to Protein Depletion HARRY H. L. VEEN and WILLIAM H. FISHDAM. *Ann. Surg.* 1943, 17: 352.

The protein reservoir in the form of total circulating plasma proteins, although partially dependent upon the concentration of plasma proteins, cannot be assessed by isolated plasma protein value. The total circulating protein per square meter of surface area is lower in hypoproteincemic patients.

The precipitable saline soluble liver protein per unit of protein structural mass (ratio of precipitable saline soluble to saline insoluble protein) is maintained at a relatively constant level between 1 and 2 gm. per gram of structural protein. The constancy of this ratio suggests that there are definite protein storage limitations in the liver and also that a certain quantity of precipitable saline soluble protein is retained by the liver cell for preservation of vital functions. The variations between 1 and 2 gm. per unit of structural mass allows for a maximum possible storage capacity of 2.38 gm. of protein in a 1,500 gm. liver. That such storage actually occurs at least temporarily was illustrated by one patient receiving a large plasma and blood transfusion.

Since most ratios of precipitable saline soluble to saline insoluble liver protein are maintained closely in the region of 1.5 it is unlikely that ratios raised by plasma infusions remain high for more than a short time. Because this ratio is fairly constant there is a relatively large stationary protein mass in the liver. Such a situation tends to mask any small changes in protein concentration which may occur and may have led some investigators to believe that there is no relationship between the blood and liver proteins.

The fact that liver proteins participate in alterations occurring in plasma proteins is evident from the data presented. The rapidity with which changes may occur is demonstrable in experiments on dogs. The results of both studies are therefore in harmony.

Septicemia Due to the Proteus Vulgaris. HERBERT L. ABRAHAM. *A. England J. M.* 1945, 238: 35.

Proteus vulgaris is usually considered nonpathogenic and is commonly found in normal feces, however it has been implicated in a large number of pathologic states and has produced septicemia in a few cases. Data on 52 cases of *Proteus* septicemia collected from the literature are summarized. Cases have been reported at all ages, although most of them occurred during the third decade. 44.7 per cent of the cases originated in the ear, nose, or throat and 46.8 per cent originated in the genitourinary

tract. The characteristic pathological finding was the foul-smelling green or brownish-green pus in all infected areas.

Most of the patients appeared acutely ill and in a septic fever with chills, although occasionally a typhoidal type of fever curve was encountered. Leucocytosis was usual and anemia was occasional. The illness was very long in the patients who recovered, although it was usually shorter in those subjected to some operative procedure. Most of the conditions arising from the ear presented a discharge and a history of chronic otitis. Fifteen of the 52 conditions arising from the genitourinary tract occurred after operative procedures. The mortality was 80.1 per cent in those arising from the ear, nose, and throat, 36.8 per cent in those arising from the genitourinary tract and 64.6 per cent for the whole series. The diagnosis was established by positive blood culture.

The author presents one case of *Proteus* septicemia with recurrent chills and fever following cystectomy for renal calculi done 5 months before. Sulfonamides had brought a temporary remission of the fever and penicillin had had no effect. After positive blood cultures were obtained for the *Proteus vulgaris* the patient was given 0.3 gm. of streptomycin every 3 hours for 10 days, and recovery was prompt.

ROBERT MAYO THAYER, M.D.

Estrogens and Tumor Genesis. BENJAMIN ZODER. *Acta radiol. Stockh.* 1947 23: 433.

The danger of the carcinogenic effect of estrogens in man has been highly exaggerated. During 20 years of clinical experience with estrogenic hormones the author has never observed the induction of an malignant tumor in man. Cancer can be reduced in some rodent strains of high cancer susceptibility when estrogens are administered in very large doses.

However, during the past decades large numbers of women have undergone estrogen treatment for many months and even years. If there were a carcinogenic effect, the number of cancers both of the uterus and breast would certainly have been greatly increased, which has not been the case.

The most that can be deduced from animal and human experience to date is that estrogenic hormones should be administered with greater caution to patients having cystic mastitis or cervical erosion or to those belonging to families with a high cancer incidence.

FRANK B. QUINN, M.D.

Leiomyosarcoma, the Mixed Tumor of Mesenchymal Derivatives. ARTHUR PERRY STOUT. *Ann. Surg.* 1945, 7: 78.

Leiomyosarcomas are tumors made up of an amalgamation of mesenchymal elements capable of producing muscle, fat, blood vessels, cartilage or bone. The individual tumor consists of at least two of these elements and all of these tumors are actually

potentially malignant. They are usually found in ucle or subcutaneous tissues.

The author reports 8 cases and states that these ors may occur anywhere including the liver, pleura and lateral part of the neck. He also attention to the fact that they do not necessarily occur in regions where congenital malformations are to be expected such as the urogenital tract and breast. In the latter locations these tumors contain epithelial elements as well as mesodermal derivatives such as adenofibromas of the breast and be adenocarcinomas of the kidney.

Treatment begins with biopsy to determine the ture of the neoplasm. Early and radical surgery recommended when the diagnosis is made even if means amputation. EDWARD R. DOMOGAY, M.D.

EXPERIMENTAL SURGERY

Experimental and Clinical Studies of Reduced Temperatures in Injury and Repair. H. BAXTER, M. A. EDWIN and R. H. MORSE. *Plast. Reconstr. Surg.* 1948, 3: 11

In a preceding paper the authors pointed out that the study of the behavior of wound healing and tissue regeneration under the influence of reduced temperature forms an important phase of the broad investigative project encompassing the experimental and clinical study of the effects of reduced temperatures on injury and repair of human tissues. Apart from the broader aspect of the pathogenesis of injury by cold considerable interest has been stirred up in the recent literature on the effect of local reduced temperatures in a variety of conditions including the treatment of burns. Before adequate appraisal of the effect of cold on the healing of burns in man could be undertaken, it was well to know what effect cooling has on the healing of clean surgical wounds particularly with regard to the rate of epithelialization and fibrous tissue formation.

Dermatome donor sites—areas from which a uniform layer of skin was removed with the Padgett Hood dermatome—were selected for the purpose of the experimental study. Fresh dermatome donor areas have several features which make them suitable for study of effect of cold on wound healing.

(1) Uniform thickness of split-skin can be removed from two or more comparable sites, which provides standard areas where spontaneous healing with tissue formation and epithelialization can occur.

(2) It is possible to vary the time required for spontaneous healing by removing thinner or thicker layers of skin.

(3) The behavior and rate of epithelialization have been extensively studied and a standard type of dressing giving optimal spontaneous healing is now used routinely in skin grafting which provides a condition in which alteration of the temperature of the environment is the only variable factor.

(4) In spite of the obvious difference of the two conditions dermatome donor areas are somewhat similar to moderate burns of the skin because in both

cases skin is destroyed to a certain depth and re-epithelialization of the area, apart from the proliferation from the edges of the wound takes place from the portion where the hair follicles sweat glands and ducts remain intact.

Donor areas on the anterolateral aspects of the thighs in the healthy adult were selected for this experimental study. The cooling was obtained by placing the entire limb into a special apparatus constructed for that purpose. The apparatus had two chambers in one of which cold air circulated in a closed circuit while in the other air at room temperature was similarly kept in motion for the control limb. The alterations of the state of the vascular system of the areas under observation were determined by recording the skin temperatures with constantan-copper thermocouples sutured to the selected sites.

Donor sites were used in this series of experiments designed to study the effect of cold on wound healing a process which involves in the skin fibrous tissue formation to replace the dermis and epithelial regeneration to restore the continuity of the epidermis. Under optimum conditions the healing of a dermatome donor site from which 0.016 inch of skin had been removed occurred spontaneously in from 8 to 10 days.

The process of tissue repair is a continuous interplay of cell migration combined with structural synthesis involving a sequence of biochemical reactions. The rate of both components of this process is influenced directly by the temperatures of the environment. Within a certain range of moderate temperatures either cold or warm the sole effect will be either a reduction or an increase in the rate of these reactions of repair. However, drastic reduction or increase of the temperature brings in its wake a whole sequence of changes which complicates and interferes with the optimal process of wound healing.

The observations recorded in this series of cases presented the results of study of the processes of epithelialization and fibrous tissue formation under different temperatures and durations of exposure but under controlled conditions. Combining the cold treated and the control areas into tabular form it is apparent that in the range of temperature between 83 and 53° F the time required for complete epithelialization of the area is inversely proportional to the height of the temperature and directly proportional to the time of exposure. In the range of cold temperatures from 65° to 53° F the delay of complete epithelialization was from 3 to 4 days for the standard dermatome donor area as compared with the controls.

Precooling of the area prior to the removal of the skin was carried out in one case. This particular experiment was attempted because it has been claimed that tissue irritation and hyperemia speed the processes of healing. The skin was removed at the height of hyperemia which followed the exposure of the patient's thigh for 72 hours to 60° F. The donor site was subsequently treated with Bettman's

gauze and a pressure dressing identical to these factors for the untreated control area. Healing occurred in about the same time as in the controls and grossly there was no difference between the two areas, either in appearance or in texture. The only conclusion that the authors could draw from this observation was that exposure of the skin to 60° F for as long as 72 hours prior to removal of the skin does not delay the healing of the donor area.

The authors' observations based on the treatment of donor sites under experimental and noninvestigative conditions show that application of a pressure dressing other things being equal speeds up spontaneous epithelialization of the donor area, reduces the amount of exudate, and keeps in check the subepithelial fibrosis. The principle of pressure dressing has been advocated and followed by many workers, and its utilization in the field of plastic surgery and for the treatment of burns and other injuries has been firmly established.

There have been many advocates of cold for the treatment of burns. The authors' observations based upon the experiments with laboratory animals, and experimental and clinical study of the effect of cold in man do not bear out the enthusiasm of these investigators. Application of moderate cold delays healing even under optimum conditions of repair and regeneration. It is difficult to combine a pressure dressing with the application of cold and consequently the pressure has to be dispensed with. The degree of cold required to check bacterial growth and disintegration of the tissue imposes additional damage on the part which is already injured by heat.

Parenteral Nutrition. Studies on the Tolerance of Dogs to Intravenous Administration of Fat Emulsions. HARVEY S. COLLINS, LYSBETH M. KRAFT, THOMAS D. KIRKNEY, CHARLES S. D. VIDSON and OTHERS. *J Lab Clin Med* 94B, 33-43.

Parenteral administration of fat is a means of securing a high caloric intake in a minimum of fluid volume. The high caloric intake protects the body proteins and should considerably improve the nutritional status of severely emaciated children or adults.

Previous studies on dogs revealed granulomatous lesions in the lungs and spleen and to a lesser extent in the liver produced by a 15 per cent fat emulsion.

In the present study a 30 per cent fat emulsion stabilized with soybean phosphatides (asolectin) was given. An initial increase in plasma fat was found

but normal values were approached within an hour after the infusion.

Control experiments have shown that the soybean phosphatide used as a stabilizer was primarily responsible for the production of granulomatous lesions.

ARTHUR J. LEMER, M.D.

Parenteral Nutrition. Improved Techniques for the Preparation of Fat Emulsions for Intravenous Nutrition. ROBERT P. GRYER, GEORGE V. MARY, and FREDRICK J. STARR. *J Lab Clin Med* 194B, 11-33.

In the present study the size of the particles in fat emulsions and their stability were investigated. It appeared desirable that all particles in the emulsion used should not be larger than normal chylomicrons. A photomicrographic method for determining the size of fat particles has been developed, and by means of high pressure homogenization, fat emulsions were prepared in which all particles were below 2 microns in diameter.

It was found that high pressure, high temperature, and continuous recirculation of the material and the proper amount of the fat stabilizer aided in the preparation of fine emulsions.

ARTHUR J. LEMER, M.D.

Parenteral Nutrition. Studies on Soybean Phosphatides as Emulsifiers for Intravenous Fat Emulsions. ROBERT P. GRYER, GEORGE V. MARY, JOHN YOUNG, THOMAS D. KIRKNEY and FREDRICK J. STARR. *J Lab Clin Med* 94B, 35-163.

In this study attempts were made to eliminate the factors responsible for the granulomatous lesions which were produced by fat emulsion with a soybean phosphatide stabilizer. In experiments on albino rats and puppies it was again found that soybean phosphatide was the agent chiefly responsible for the production of granulomatous lesions.

Since previous studies have shown that the soybean was the best emulsifying agent, a chemical fractionation of the soybean phosphatide was attempted in order to find a fraction with good emulsifying, but little or no lesion-producing qualities.

In the final experiment 3 puppies received daily intravenous infusions of a 30 per cent fat emulsion prepared with a soybean fraction B (F₂) obtained from a diethylether solution by a process described in detail by the authors. The experiment lasted from 3 to 84 days, and none of the puppies showed granulomatous lesions.

EVOLUTION AND TREATMENT OF TUBERCULOSIS OF THE HIP

IGNACIO PONSETI M.D. Iowa City Iowa

THE evolution of tuberculosis of the hip joint in patients seen in this clinic has been studied to determine the results of conservative and operative treatment as well as the optimum time for surgery and the efficiency of different surgical operations.

Thirty-one proved cases of tuberculosis of the hip followed for a minimal period of 4 years were chosen for this study. The tuberculous nature of the hip lesion was proved by positive guinea pig reactions to inoculations of abscess material or of tissue from the involved hip. In some instances the *Bacillus tuberculosis* was found on direct smear or in cultures of this material. Lesions of proved tuberculous nature in the viscera or other osteoarticular regions in patients with hip joint involvement were also considered as proof of the tuberculous nature of the hip joint lesion. Microscopic sections of tissue of the hip joint which showed pathological lesions described as typical of tuberculosis were not accepted as definite proof of the tuberculous nature of the process unless a positive reaction in guinea test was obtained from the same tissues. Granulomatous and necrotic lesions similar to those seen in tuberculosis can be produced by other organisms than the Koch bacillus.

The 31 cases chosen for this study do not represent a true cross section of the different

types of hip tuberculosis seen in this clinic. It is usually difficult to prove the tuberculous nature of hip lesions which are of very slow development and show no abscess formation and which develop in patients who are in good general condition and who years before the onset of the hip symptoms had minimal and clinically undetected pulmonary lesions. Many of these patients who had a probable but not proved tuberculous hip necessarily had to be excluded from our series whereas cases of patients with hip lesions of acute onset and stormy evolution were easily proved and many could be included in this study. However since the diagnosis of osteoarticular tuberculosis is so inaccurate when made on clinical and roentgenographic studies alone we have preferred to discard all the unproved cases even if by so doing the statistics do not represent a true picture of the different types of tuberculous hip disease. Many cases in which the follow up extended over a short period only or there was no follow up were also discarded.

For this study the cases were divided into three groups:

- 1 Primary para articular bone lesions—7 patients, all children
- 2 Tuberculosis of the hip joint in childhood (under 15 years of age)—15 patients.
- 3 Tuberculosis of the hip joint originating in the adult—9 patients 1 with bilateral hip tuberculosis.

From the Department of Orthopedic Surgery, State University of Iowa Hospitals.

Fig. a, Roentgenogram of the left hip of 6-year-old boy shows an area of uniform bone destruction to the inner aspect of acetabular roof. The patient had mild pain in his left leg and limp for 6 months. Hip motion, as somewhat restricted in all directions. Roentgenograms of chest showed Gohn complex, which healed and calcified 1 1/2 years. A diagnosis of tuberculous osteitis of the ilium was made. The patient was immobilized in plaster hip spica for 3 1/2 years. b, Roentgenogram taken 3 years later shows the osteitic lesion practically healed. The patient had been

ambulatory for 3 1/2 years and had no symptoms. Roentgenogram taken 1 year later shows new activity in the area of the old lesion, and enlargement of the area of destruction. The joint space is somewhat narrow and there is generalized bone atrophy. Seven months before this picture was taken the patient started to have pain again and to limp on left leg. An intra-articular and extra-articular fusion and subtrochanteric osteotomy were done 1 month later. The synovium is moderately infiltrated with tuberculous granulation tissue. The superficial layers of joint cartilage are eroded.

From a pathological point of view there is no sound basis for studying osteoarticular tuberculosis in children in a group separate from the adults. Types of destruction of similar character can be seen in children as in adults because it is not the age which regulates the different types of osteoarticular tuberculosis but the date of the primary infection (6). However, it is usually in children in whom we see the most actively destructive lesions because contacts with the *Bacillus tuberculosis* occur early in life in a great proportion of the population. On the other hand, the anatomical and physiological characteristics of the osteoarticular system and its capacity for repair change with the years. In tuberculosis as in any other infectious processes of the bones and joints the evolution of the process

PATIENTS WITH PRIMARY PARA-ARTICULAR BONE LESIONS

A circumscribed area of bone destruction close to the hip joint was observed in 7 patients, all of them children—5 boys and 2 girls. Their ages at the onset of symptoms varied from 1 to 5 years. In 3 patients the lesion was localized in the femoral neck, close to the metaphysis, whereas in the other 4 patients the lesion was located in the ilium, close to the roof of the acetabular cavity. No primary foci of

Fig 2 a, Roentgenogram of the right hip of a 6 year old boy. There is a focus of irregular bone destruction in the inner aspect of the femoral neck. The head of the femur is somewhat separated from the inner wall of the acetabular cavity. Seven months previously following a fall the patient awoke at night screaming with sharp pain in right hip. This pain reappeared periodically. He had a limp due to pain and to flexion contracture in the hip. b, The lesion in the femoral neck consisted of an extensive area of primary caseation necrosis containing sequestered bone. c, The synovia in the lower aspect of the joint was very thick and contained abundant tuberculous granulation tissue with no caseation. The guinea pig test was positive for tuberculosis.

depending on the age of the lesion. An area of surrounding sclerosis represents limitation of the process which appears when the lesion has already been present several months. Biopsy in one of these lesions revealed tuberculous granulation tissue occupying the marrow spaces and eroding and destroying the bone trabeculae. Small areas of caseation were very scarce in the granulation tissue.

In the 4 remaining patients the roentgenograms showed the area of bone destruction to be partially filled with one or several dense bone sequestra of different size and shape (Figs 2, 3 and 4). A wall of dense bone was seen surrounding this area. The biopsy in 2 of these cases showed these sequestra to be formed by dense trabeculae of dead bone. The marrow spaces were occupied by caseated marrow tissue with some of its structures still faintly discernible in places, indicating

that the lesion represented a primary caseation of the marrow (Fig 2b). Surrounding the sequestra were caseated material and debris with a few scattered areas of tuberculous granulation tissue, polynuclears and chronic inflammatory cells. The first type of lesions was designated granulous osteitis, because of the abundance of tuberculous granulation tissue. The last type of lesions is called caseous osteitis because of the abundance of primary caseation necrosis of the marrow tissues (6 to 11).

In most children there was a tendency for both types of tuberculous osteitis treated conservatively to become limited and walled off. The bone sequestra were slowly destroyed and later new bone trabeculae filled in the cavity (Fig 4). In a few years the old lesion had disappeared from the roentgenograms. In certain cases however the lesion reap-

Fig. 3. Roentgenogram of 4 ear old girl, two months previous, the patient started limp and continuous pain in the left hip. The best negative Bloper showed extensive focus of caseous necrosis in the ilium containing large bone sequestrum. The guinea pig test as positive for tuberculosis.

peared and even enlarged when immobilization was discontinued and weight bearing and freedom of motion were resumed. Even if the primary focus of osteitis disappeared completely the hip joint in each of the 7 patients was affected sooner or later by the tuberculous process regardless of treatment. It was very difficult from clinical and roentgenographic examinations to ascertain when the hip joint was first invaded by the spreading of the focus of tuberculous osteitis. We have never seen a patient with a focus of osteitis adjacent to the hip joint complaining of only osteocopic pain, but invariably pain of arthritic character was present on admission. The patient may have occasional pain in the hip and a slight limp and he often cries at night. On clinical examination a few degrees of limitation of motion are noted and pain accompanies extreme degrees of motion. The roentgenograms show a localized osteitis with a seemingly normal hip joint. However when biopsy is done at this time the synovia adjacent to the bone lesion is found already invaded by tuberculous granulation tissue (Fig. 2).

Further joint involvement may proceed in a slow progressive manner or the joint may

become rapidly destroyed a few months after the onset of the osteitic lesion. In 3 of our patients roentgenographic evidences of joint destruction were not seen until 1½ to 4½ years after the onset of symptoms. The roentgenograms later on showed further narrowing of the joint space with some marginal bone destruction atrophy and irregular minimal spotty destruction of the subchondral bone, and generalized bone atrophy. The limitation of motion in the hip progressed the hip pain became more continuous, the child limped markedly and flexion and adduction contractures of the hip joint developed and progressed slowly. One patient had sharp increase of pain and some fever 4 years after onset of symptoms. The roentgenograms, which had been showing a slowly progressive joint destruction revealed marked increase of bone destruction a few weeks after the acute episode a wandering acetabulum and extreme bone atrophy (Fig. 4). The pathological examination of the joints which were slowly destroyed by the tuberculous process showed the synovia replaced by thick tuberculous granulation tissue with many typical tubercles present. Caseation of the tubercles was very rare. At the joint margins granulation tissue formed a pannus creeping over the joint surface and eroding the joint cartilage. The subchondral bone showed osteoporosis and nonspecific granulation tissue was slowly destroying the bone cartilage from underneath. Very rarely were miliary tubercles found in the subchondral spaces. Overgrowth of hyaline and fibrocartilage was seen at the periphery of the joint in one instance (Fig. 6).

In 4 of our patients the hip joint was involved and rapidly destroyed only a few months after the onset of symptoms from a para articular focus of osteitis. In 2 of these patients the joint was involved following biopsy and removal of the focus of osteitis, 1 and 10 months after the onset of symptoms. The joints in both cases were completely destroyed after a few months of a stormy post-operative course with fever pain increased sedimentation rate, and elevated white blood count. In the other 2 patients the joints became ostensibly involved as seen on the roentgenograms, and were rapidly destroyed and

Fig. 4, a, Roentgenogram of the left hip of a 22-month-old boy taken on September 23, 1940. It shows a focus of osteitis in the femoral metaphysis containing one sequestrum. The child limped on left leg when he began to walk at 11 months of age. Occasionally complained of pain in the hip which was in 30 degrees flexion contracture. The patient was immobilized in plaster hip spica. b, Roentgenogram taken on May 16, 1941 shows that the bone sequestra are being absorbed. The joint space is somewhat narrow. Later on the patient was symptomless and began to walk in July 1943. Half a year later he developed flexion contracture in same hip. c, Roentgenogram taken on May 1, 1944 shows the lesion of the femoral metaphysis to be healed. However the upper joint space is narrow and the femoral head is separated from the inner wall of the acetabular cavity. Subchondral cystic destruction is seen in the femoral head. The patient was again immobilized. d, Roentgenogram taken in July 1945 shows advanced destruction of the femoral head and acetabular roof. e, Roentgenogram taken on January 14, 1946, 6 months after a British operation. The bone graft is seen eroded and fractured. A soft tissue abscess is present medial to the upper femoral shaft, at the site of the bone graft. Guinea pig test was

positive for tuberculosis. The patient is still under treatment.

5 months after the onset of symptoms due to the fast spreading of the focus of osteitis (Fig. 5). The joint invasions in these cases were characterized by very acute clinical symptoms such as an extreme amount of pain, high temperature—103 degrees, complete fixation of the joint due to muscle spasm, elevated white blood count, elevated sedimentation rate and low hemoglobin. Great destruction of the femoral head and of the acetabular roof could be seen a few months later in the roentgenograms. The pathological examination in one of these patients showed the predominance of caseation necrosis in the synovia and in the subchondral bone with destruction of the joint cartilage.

According to our experience the type of pathological lesions seen in the involved joint

was not always of the same character as in the lesions found in the original focus of osteitis. Biopsy in 2 patients for example with an extra articular tuberculous focus showed the bone lesion to be a caseous osteitis as it was formed by bone sequestra surrounded by caseated marrow with no tubercles. The synovia adjacent to this focus of bone destruction showed on the other hand tuberculous granulation tissue with typical tubercles and no caseation (Figs. 2 and 3). However the joint became rapidly destroyed in both cases after caseous material was implanted into the joint at the time of operation.

The causes for the predominance of the caseous or the granulous type of lesions in tuberculous osteitis and osteoarthritis are obscure but probably are related to changing allergic

Fig. 3. Roentgenogram of 44-year-old port 54-month previously the patient started to limp and to have marked and continuous pain in the left hip. The best negative biopsy showed extensive focus of caseous necrosis in the ilium containing large bone sequestrum. The guinea pig test as positive for tuberculous.

peared and even enlarged when immobilization was discontinued and weight bearing and freedom of motion were resumed. Even if the primary focus of osteitis disappeared completely the hip joint in each of the 7 patients was affected sooner or later by the tuberculous process regardless of treatment. It was very difficult from clinical and roentgenographic examinations to ascertain when the hip joint was first invaded by the spreading of the focus of tuberculous osteitis. We have never seen a patient with a focus of osteitis adjacent to the hip joint complaining of only osteocopic pain, but invariably pain of arthritic character was present on admission. The patient may have occasional pain in the hip and a slight limp and be often cries at night. On clinical examination a few degrees of limitation of motion are noted and pain accompanies extreme degrees of motion. The roentgenograms show a localized osteitis with a seemingly normal hip joint. However when biopsy is done at this time the synovia adjacent to the bone lesion is found already invaded by tuberculous granulation tissue (Fig. 2).

Further joint involvement may proceed in a slow progressive manner or the joint may

become rapidly destroyed a few months after the onset of the osteitic lesion. In 3 of our patients roentgenographic evidences of joint destruction were not seen until $1\frac{1}{2}$ to $4\frac{1}{2}$ years after the onset of symptoms. The roentgenograms later on showed further narrowing of the joint space with some marginal bone destruction, atrophy and irregular mottled spotty destruction of the subchondral bone, and generalized bone atrophy. The limitation of motion in the hip progressed, the hip pain became more continuous, the child limped markedly and flexion and adduction contractures of the hip joint developed and progressed slowly. One patient had sharp increase of pain and some fever 4 years after onset of symptoms. The roentgenograms, which had been showing a slowly progressive joint destruction revealed marked increase of bone destruction a few weeks after the acute episode a wandering artetabulum and extreme bone atrophy (Fig. 4). The pathological examination of the joints which were slowly destroyed by the tuberculous process showed the synovia replaced by thick tuberculous granulation tissue with many typical tubercles present. Caseation of the tubercles was very rare. At the joint margins, granulation tissue formed a pannus creeping over the joint surface and eroding the joint cartilage. The subchondral bone showed osteoporosis and nonspecific granulation tissue was slowly destroying the bone cartilage from underneath. According to our experience the type of pathological lesions seen in the involved joint

was not always of the same character as in the lesions found in the original focus of osteitis. Biopsy in 2 patients for example with an extra articular tuberculous focus showed the bone lesion to be a caseous osteitis as it was formed by bone sequestra surrounded by caseated marrow with no tubercles. The synovia adjacent to this focus of bone destruction showed on the other hand tuberculous granulation tissue with typical tubercles and no caseation (Figs. 2 and 3). However the joint became rapidly destroyed in both cases after caseous material was implanted into the joint at the time of operation.

The causes for the predominance of the caseous or the granulous type of lesions in tuberculous osteitis and osteoarthritis are obscure but probably are related to changing allergic

Fig. 5. a, Roentgenogram of a 3-year-old boy showing small area of destruction in the acetabular roof. The patient had mild pain in the right hip and knee for 1 month. Shortly after this roentgenogram was taken the patient fell and injured the right hip. After that he started to have high temperature and great deal of pain in the same hip. The osteitic lesion had opened into the hip joint. The patient was then immobilized in a hip spica cast. b, Roentgenogram taken 10 months later. The hip joint had been destroyed. A new acetabular roof is readily delimited. c, Roentgenogram taken 2 years later, just before surgery. What was left of the femoral head and acetabulum appear well recognized. The joint space is very dense and contains several sequestra. The patient died of shock shortly after surgery. Examination of the hip showed the joint space to be occupied mostly by hyaline cartilage and fibrocartilage. A few pieces of dead bone are lying destroyed in granulation tissue. Area of cavitation necrosis partially calcified, were seen here and there. A few tubercles surrounded by concentric layers of fibrous tissue were also seen.

conditions in the patient (6). However it must be emphasized that only in the early stages of osteitis or synovitis can pure caseous or granulous lesions be found. These two types of tuberculous lesions will be seen intermingled sooner or later in any tuberculous process although one of the lesions will predominate over the other (5, 9).

According to our experience, once the hip joint became involved it either fused spontaneously or a fusion operation had to be performed. This was necessary because of persistent pain, increasing joint destruction and flexion and adduction contractures. Four patients were treated by prolonged immobilization in plaster casts—two hips became ankylosed 3 years after onset of symptoms due to the focus of osteitis and approximately $2\frac{3}{4}$ years after the joint invasion. The other 2 hips did not become ankylosed until $3\frac{1}{2}$ and 5 years after the joint invasion. Obviously the joints rapidly destroyed by a caseous process became ankylosed faster than the joints which were slowly destroyed by a granulomatous type of lesions. Three patients were operated upon. A Britain fusion was performed

In 1 patient 5 years after the onset of symptoms and failed because of absorption of the bone graft. This patient is still under treatment. An intra-articular and extra-articular fusion plus a subtrochanteric osteotomy has been performed recently in another patient 5 years after the onset of symptoms. An extra-articular fusion was performed in 1934 on another patient 3 years after the joint invasion. The patient died of shock shortly after the operation.

The following observations taken from this study concerning the evolution of tuberculous para-articular foci about the hip joint are in agreement with those in most of the reports in the literature.

1. Extra-articular foci of osteitis are seen more often in children and very rarely in adults.
2. The femoral head is almost never involved by a primary focus of tuberculous osteitis.
3. The hip joint becomes involved sooner or later in the great majority of patients, regardless of whether the treatment of the focus of osteitis has been conservative or operative.

Fig. 6. a, Roentgenogram of the right hip of a 4 year old boy taken in October, 1931. There is atrophy of the upper femur and pelvis, and an area of bone destruction with irregular dense calcification is seen in the femoral neck. The patient limped and had pain in right knee and hip for 5 months. The right hip was in marked flexion, abduction, and outward rotation contracture. The right leg was placed in traction and later in a hip spica plaster cast. b, Roentgenogram taken 2 years later shows that the lesion in the femoral neck has been displaced distally due to the growth of bone at the epiphyseal plate. The contours of the lesion are less sharp. The upper femur is very atrophic and the joint capsule is distended. The femoral head is somewhat flat and the subchondral bone is irregular. c, Roentgenogram taken 4 years after onset of symptoms. The lesion of

the femoral neck has disappeared. The joint space is narrow. There is a new area of bone destruction in the outer aspect of the femoral head. Biopsy and exploration of the hip were performed at this stage. d, Represents the outer margin of the femoral head. There is overgrowth of hyaline cartilage at the area of bone destruction seen in the roentgenogram. A pannus formed of granulation tissue and fibrous tissue was covering the surface of the joint cartilage (the wrinkling of the pannus is an artefact). There is chronic, and for the most part nonspecific, granulation tissue in the marrow spaces of the subchondral bone. The capsule was thickly infiltrated by tuberculous granulation tissue with many typical tubercles. Caseation of the tubercles was rarely seen. Guinea pig inoculation was positive for tuberculosis.

Hatcher and Phemister reported that in only 2 of 26 children did the lesion which was centrally located in the femoral metaphysis heal without joint involvement. Cholmeley reported that of 55 patients only 3 recovered with an intact hip joint. 1 had a focus of osteitis in the greater trochanter which was removed surgically and in the 2 others the lesion was localized in the ilium over the cotyloid rim and in the medial wall of the acetabulum.

From these findings we know then that the focus of tuberculous osteitis about the hip joint will take years to heal if conservative treatment with plaster cast immobilization is employed but in spite of this treatment the joint will become involved in the great majority of cases. Drainage and curettage of the focus of osteitis will not save the joint either unless the focus is located in the greater trochanter or occasionally in the ilium at some distance from the hip joint. Based on this experience we believe that treatment of the focus of tuberculous osteitis close to the hip joint must be directed toward obtaining an ankylosed joint as soon as there is clear evidence that the destructive process of osteitis remains well localized and the general condition of the patient is satisfactory. Care should be taken not to disturb the focus of osteitis a step easily accomplished when the focus of osteitis is located either in the medial aspect of the femoral neck, ischium, or in the middle aspect of the ilium. However if the focus of osteitis is located in the lateral aspect of the femoral neck or of the acetabulum a hip fusion operation will necessarily disturb the osteitic lesion and the tuberculous process may be exacerbated and may spread widely. It may be wise in these cases to delay surgery until the healing of the osteitis is well advanced.

TUBERCULOSIS OF THE HIP JOINT IN CHILDREN

Fifteen patients with tuberculous arthritis of the hip joint which started during childhood were studied. Eight were seen from 1 to 10 months after the onset of symptoms and no foci of osteitis were present on the roentgenograms, a fact suggesting a synovial origin of the tuberculous process. Seven patients were seen from 1 to 50 years after the onset

of symptoms. The hip joint in these patients was extensively destroyed on admission so that it was not possible to ascertain if the tuberculous arthritis had originated from a focus of osteitis or from a primary synovial tuberculosis. The ages of the patients at the time of onset of symptoms varied from 1 to 12 years, 5 years being the average.

Röntgenograms of the chest were taken on admission in all patients and at least every year while under our supervision. Five patients from 2 to 11 years of age had pulmonary lesions with the characteristics of a primary complex. This lesion was healed on admission in 3 patients and in the other 2 healing rapidly progressed. The chest plates of 7 patients never showed any tuberculous lesions while under our treatment although in 2 of them there was some perihilar infiltration. Two patients developed new pulmonary tuberculous lesions 12 and 14 years after the onset of the hip lesion. One patient died of miliary tuberculosis 1½ years after onset of the hip tuberculosis. Two patients developed tuberculosis of the spine 14 and 50 years after the tuberculosis of the hip.

The onset of hip tuberculosis in children was usually insidious during the first few weeks or months. The patients often cried at night and had slight limp but the hip was painless during the day time. Later on the hip pain became acute and constant and there was fever which went up as high as 104 degrees in some instances. The patients limped badly, weight bearing being sometimes impossible because of pain. The patients lost weight, the thigh became markedly atrophic and contracture deformities of the hip developed in a few weeks or in a slow manner in several months. In 12 patients the leg was in marked flexion and adduction, contracture on admission and in 3 patients the thigh was in marked flexion, abduction, and outward rotation. There were only a few degrees of motion in the hip joint of most patients, due to pain and muscle spasm. The sedimentation rate was increased and the hemoglobin and red blood count were low. The elevated white blood count was invariably related to the development of an abscess and in some patients it reached as high as 16,000. The guinea pig inoculation with fluid obtained

Fig. 7 a, Roentgenogram of the right hip of a 6 year old patient, taken in September 1939. The subchondral bone of the femoral head and acetabulum appear destroyed. The joint space is wide. The patient started to limp 3 months before this picture was taken and had acute pain in the hip during the last 2 weeks. The leg was in flexion and adduction contracture. There was an abscess in the adductory region, which was aspirated. The acid-fast smear and the guinea pig inoculation were positive. Traction was applied on the right leg for 1 week, followed by plaster hip spica. b, Roentgenogram taken 9 months later. The joint space is very narrow and the shadow of an abscess is seen between the ilium and the femur. c, Roentgenogram taken 1 year and 8 months after onset of symptoms. It shows re-ossification of the femoral head and ilium. The joint space is still very narrow. The general condition of the patient was good. In May 1941 a subtrochanteric osteotomy was performed (Farinas). d, Roentgenogram taken 3 months after osteotomy. The joint space has started to become

wider. The femoral head shows a focus of bone destruction. There were a few degrees of painless motion in the hip. e, Roentgenogram taken 3 years after onset of symptoms shows very wide joint space and some activity of the tuberculous process in the femoral head. There was no pain or muscle spasm and range of motion in the hip was fairly good. The patient was then allowed to walk on crutches. f, Roentgenogram taken 1 year later shows advanced destruction of the femoral head. The joint space remains wide. The patient had some pain and recurrence of the adduction and flexion contractures. An extra-articular arthrodesis was performed 2 months later. g, Roentgenogram taken 3 months after the extra-articular arthrodesis. There is no longer bony contact between the tibial grafts and the trochanter. The joint space remains wide. Another extra-articular fusion had to be performed in April, 1944. h, Roentgenogram taken 1 year and 10 months after the second extra-articular fusion. Bony fusion has not yet become solid.

from the joint or from the abscess was positive in 10 patients negative in 1 and it was not taken in 4 patients. In 5 patients Corper's media culture of the joint or abscess material

was positive and in 3 patients the direct smear was positive. No attempts were made to differentiate between the human and bovine types of *Bacillus tuberculosis*.

Fig. 8. a, Roentgenogram of the right hip of a 4 year old boy who had pain in this hip and limped for 9 months. The femoral head appears to be subluxated posteriorly. The acetabular roof is destroyed. The right leg was in extreme flexion and abduction contracture. Traction was applied on the right leg for 4 months, followed by plaster hip spica. A warm abscess appeared 6 months later on the posterolateral aspect of the hip region. The abscess was aspirated, ice and sinus opened and drained for 2 months. The acid-fast smear and guinea pig inoculation were positive for tuberculous. b, Roentgenogram taken 1 year later shows the femoral head to be replaced in the acetabular cavity. The joint space is hazy and narrow. c, Roentgenogram taken 3 years and 3 months after onset of symptoms shows a well advanced reorganization of the iliac bone and upper femur. The contours of the femoral head and upper acetabulum are well delineated. The joint space is wide. There is some painless motion in the hip. An extra-articu-

lar arthrodesis was performed at that time. d, Roentgenogram taken 3 months after extra-articular fusion. Bone atrophy of the middle portion of the bone graft is already evident. Roentgenogram taken 9 months after the operation. The middle portion of the bone graft has been completely absorbed. The joint space is very wide. The femur appears abducted. A second extra-articular arthrodesis was then performed. The new bone graft also became reabsorbed in its middle portion but a few months later new bone trabeculae bridged the defect. A subtrochanteric osteotomy had to be performed 1 year after the second arthrodesis operation in order to correct a progressive abduction contracture. f, Roentgenogram taken 14 years after the second extra-articular arthrodesis. The middle portion of the bone graft which was applied at the time of the second operation is atrophic. The joint space is still visible. Clinically there was no motion nor pain in the hip joint.

The roentgenograms of children who were seen early in the evolution of the tuberculous process showed that the hip joint was rapidly destroyed in all the patients. The joint space became narrow a few months after the onset of symptoms. Shortly after there was exten-

sive destruction of the bone of the acetabular cavity and of the femoral head. There was generalized bone atrophy of the iliac bone and upper femur.

In several instances it was found the joint space became wider and the joint capsule ap-

Fig. 9. a, Roentgenogram of the left hip of a 2 year old boy taken 4 months after acute onset of pain in the hip and femur. The femoral head and acetabulum appear completely destroyed. The patient had refused to walk since onset of pain. On admission the left leg was in flexion abduction and outward rotation contracture and any attempt to move the hip caused great pain. The left leg was placed in traction for 2 weeks and then in a plaster hip spica. An abscess developed in the lateral aspect of the thigh 1 year after onset of symptoms. This was aspirated once and the guinea pig test was positive for tuberculosis. b, Roentgenograms taken 2 years and 8 months after onset of symptoms. New dense bone trabeculae are seen in the trochanteric region and in the femoral neck. A newly formed acetabular roof appears dense and well outlined. The joint space is wide. c, Represents a low power photomicrograph of a portion of the surface of the femoral head covered by a thick layer of fibrous tissue. This specimen was obtained during the hip fusion performed shortly after the stage represented by Figure 9b. The entire joint cartilage had disappeared during the active stage of the disease. No signs of tuberculous activity can be seen in the subchondral bone or in the fibrous tissue covering it. This fibrous tissue which also covered the acetabular roof was completely removed at the time of surgery and the joint space was packed with bone grafts from the tibia and ilium. d, Roentgenogram taken 3 months after intra-articular and extra-articular arthrodesis. The hip is already solidly fused. The femur was placed in 20 degrees abduction to compensate for the shortening of the left leg. e, Roentgenograms taken 2 1/2 years after surgery. The hip is well fused and the tuber-

culous process is healed. The position of the femur in abduction had not changed.

peared distended during the first months of the disease due to the collection of debris and caseous material inside the joint. The subchondral bone appeared irregularly destroyed and atrophic in these hips. It was not until a few months later that the joint capsule burst open and the intra-articular debris emptied into the soft tissues forming an abscess. The joint space then became narrow and it was possible for what was left of the bone of the femoral head to establish contact with the irregular acetabular roof (Figs. 7, 8 and 9)

In 12 children a tuberculous abscess was seen on admission or it became ostensible while under treatment from 3 months to 3 years after onset of symptoms. 14 months was the average period. In 4 patients the abscess could be seen on the roentgenograms but they could not be detected by clinical examination.

When the tuberculosis of the hip joint was very active the abscess was big, warm, difficult to visualize on the roentgenograms and had a tendency to break through the aponeu-

Fig. 8. Roentgenogram of 53-year-old man who had a large loss of the hip joint because of tuberculosis. There was slight springy motion in the hip joint and the thigh was 5 degrees abduction and 30 degrees flexion. The patient had a flare-up of the hip process during the last 6 months of several months' duration. He had a draining sinus formed in the iliac crest. He had no osteomyelitis. It was proposed that the patient have a resection of the hip joint.

rosis and the skin. On the other hand, when the tuberculous lesion improved the abscess became well delimited and cauterized on the roentgenograms an opalescent shadow sometimes quite dense. (6) In 8 patients the abscess became absorbed and disappeared in 2 to 5 years; it was necessary to aspirate the abscess several times in 3 of these patients.

Four patients seen by us from 1 to 50 years after onset of symptoms developed draining sinuses which persisted for several years. The probable causes for the persistence of the draining sinuses were as follows: Intra-articular sequestrum were seen on the roentgenograms of 2 patients whose hips were secondarily infected. The drainage ceased in one of these patients after extrusion of the sequestra and spontaneous ankylosis of the hip joint, whereas draining sinuses reopened for 5 years off and on in the other patient who still has motion in the hip joint. A 9-year-old patient was seen in this clinic 4 years after onset of his symptoms, with a draining sinus over the iliac crest of 2 years' duration. The roentgenograms showed extensive destruction of the hip joint and bone sclerosis over the iliac wing along the sinus tract. Extensive immobilization and repeated sinus resections failed to control the drainage which was due to secondary infection. The hip joint became ankylosed

6 years after admission but the drainage persisted. The patient died of generalized amyloidosis 15 years after onset of the hip disease.

Another patient was a 52-year-old male who had had tuberculosis of the hip joint ever since the age of 2 years and had had a draining sinus during short periods of his life. The thigh was in a position of 50 degrees adduction and the hip joint which was completely destroyed, never became ankylosed because of the faulty position of the leg into adduction. The tuberculous process became reactivated periodically (Fig. 10).

In all the patients seen during the first 2 years of the disease the faulty position of the hip was easily overcome in a few weeks of traction, and then plaster cast immobilization controlled the pain and gave comfort to the patient. The general condition of the patients improved slowly. In only 1 patient was a recrudescence of the lesion observed which occurred 1 year after the onset of treatment. The roentgenograms taken during the second year of the hip disease showed reossification of the atrophic bone. Portions of the femoral head and acetabulum which appeared as if

Fig. 9. Roentgenogram of the left hip of a 24-year-old woman who had tuberculosis of the hip 10 years of age. The patient received no treatment. The hip had been asymptomatic for 10 years when first saw her and remained so during the 13 years of follow-up in this clinic. The patient was treated for tuberculosis of the spine and lungs, and the hip remained asymptomatic and freely movable.

they had been destroyed during the acute stage also became reossified. This reossification was usually irregular and a few dense new bone trabeculae were seen crossing the atrophic area. The bone contours became well demarcated and the shadow cast by the tuberculous abscess became denser, evidently due to deposition of calcium salts in the caseated debris (Figs 7, 8 and 9). Clinically there was simultaneous improvement of local and general symptoms. The joint motion although limited was painless and no pain or muscle spasm was produced when the leg was gently shaken by the foot. There was no fever and the sedimentation rate, red blood count and hemoglobin approached normal readings. The tuberculous abscess if present became smaller. The white blood count remained somewhat elevated until the tuberculous abscess disappeared completely. This clinical improvement together with the reossification of the atrophic and partially destroyed bone occurred in 8 patients from 1½ to 2½ years after onset of symptoms. In 2 patients it occurred 3 years and in 1 patient 4 years after onset. One patient died of miliary tuberculosis and another had a secondary hip infection and died of amyloidosis. Two patients came to us years after the onset of disease and it was not possible to ascertain when this healing reaction had appeared.

During this stage of reossification the joint space remained narrow but in the roentgenograms taken a few months later it was seen in 8 patients that the joint space was becoming wider (Figs. 7 and 8). This widening of the joint space was remarkable in 2 patients who were allowed early hip motion. It was also seen in patients who were immobilized in plaster cast and remained in bed for long periods. Lorenz advised the practice of very early weight bearing and ambulatory treatment to his patients immobilized in plaster cast in order to bring the bone of the femoral head and the acetabulum into close contact thus favoring early joint ankylosis. This practice has not been followed by many orthopedists because early weight bearing may often reactivate the hip tuberculosis.

Material for histologic study was obtained from all the patients operated upon but in

Fig. 2. Roentgenogram of the left hip of a 62 year old woman taken 3 months after an intra articular and extra articular arthrodesis plus subtrochanteric osteotomy. The hip was solidly ankylosed. Notice that after the osteotomy the upper femoral fragment went into abduction due to the action of the gluteus medius, thus determining pressure stresses over the extra-articular bone graft and over the denuded hip joint area. This stimulated new bone formation and resulted in fusion.

only 4 patients who had an intra articular and extra articular fusion were we able to study the hip joint well. Three of these patients were operated upon 2 to 4 years after onset of symptoms and 1 patient was operated upon 14 years after. The synovia and joint capsule were fibrotic thickened and adherent to each other. In the midst of the scar tissue small encapsulated foci were seen with necrotic cells and a few epithelioid cells. Foam cells containing lipid substance were also seen in 2 instances. Extensive portions of the joint cartilage had been destroyed and the remaining cartilage was invaded by nonspecific granulation tissue. There was fibrosis of the marrow which contained only a few tubercles well surrounded by connective tissue. Small areas of caseous necrosis were being substituted by young connective tissue. Active new bone formation was widespread. The joint space was wide in 2 patients due to thick and poorly vascular fibrous tissue and fibrocartilage which covered the femoral head and acetabulum (Fig. 9c). This fibrocartilage

Fig. 3 a, Roentgenogram of a 5 year old woman who had pain in the left hip off and on for 5 years. The joint space is very narrow and there has been minimal destruction of the femoral head and acetabulum. The patient has healed pulmonary tuberculosis. b, Roentgenogram taken 1 year after extra-articular fusion. The patient started walking 3 years after the operation and had no pain nor motion in the hip. c, Roentgenogram taken 5 years after fusion. The hip is solidly ankylosed.

was being slowly invaded by marrow tongues and new bone trabeculae.

The end results in the 15 patients with tuberculosis of the hip which started in childhood were as follows:

1. No arthrodesing operations were performed in 6 patients. The hip joint of 1 patient who had never been treated was stable, painless, and had good range of motion (Fig. 11). In another patient treated by prolonged immobilization in plaster cast the result was a freely movable but unstable hip. In 2 patients treated by plaster cast immobilization the hip became ankylosed 5 and 14 years after onset of symptoms. A 52 year old male had tuberculosis of the hip for 50 years with several flare ups and draining sinuses off and on. The leg was in 50 degrees adduction and there was slight springy motion at the hip which never became ankylosed in spite of prolonged immobilization (Fig. 10). A subtrochanteric osteotomy and adductor tenotomy were advised but the patient refused surgery. One patient died of amyloidosis after 11 years of continuous drainage from the hip which did not respond to treatment.

2. Four patients from 6 to 10 years of age were treated by immobilization in hip spica

cast followed by extra articular arthrodesis of the hip joint. Two patients were operated upon 2½ years after onset of the disease, and their hip joint became solidly ankylosed in 2 years. The 2 other patients were operated upon 4 years after onset when the roentgenograms showed a wide clear space between the femoral head and the acetabular cavity. The hip joint failed to become ankylosed in both patients and the roentgenograms taken a few months after surgery showed absorption and fracture of the bone graft. A second extra articular operation was performed on the same patients 10 months later. Solid ankylosis was not obtained until 3 and 4 years after the second operation. The fibrous tissue filling the wide joint space at the time of surgery was no doubt responsible for delaying the growth of bone trabeculae across the hip joint (Figs. 7 and 8).

3. Four patients were treated by immobilization in hip spica cast followed by intra-articular and extra articular arthrodesis of the hip joint. Three patients were from 5 to 9 years of age at time of surgery which was performed 2 to 4 years after the onset of the disease. A 26 year old female was operated upon when she came to our service because

Fig 14. a. Roentgenogram of a 31 year old woman who had pain and limitation of motion in the left hip for 6 months. Generalized bone atrophy and narrowing of the joint space can be seen. The patient had pulmonary tuberculosis for 10 years. b. Roentgenogram taken 5 months later shows extreme bone atrophy of upper femur and acetabulum, and great narrowing of the joint space. A wedge-shaped sequestrum can be seen in the upper margin of the femoral head (arrows). There was an extensive abscess around the hip joint. c. Roentgenogram taken 8 months later shows no joint space. It looks as if this had melted away. The wedge shaped sequestrum appears somewhat fragmented. There is extensive necrosis of all the marrow elements. The joint cartilage had been completely destroyed.

of a painful tuberculous hip she had had since 12 years of age. The hips of these 4 patients operated upon became solidly ankylosed from 2 to 6 months after operation, 4 months being the average. There were no operative or postoperative complications. The hips were not dislocated at the time of operation and only the fibrous tissue and fibrocartilage that could be curetted out from the periphery of the joint was removed. The denuded portion of the joint space was packed with cancellous bone and extra articular grafts were applied. Care was taken not to damage the vessels of the capsule (Fig 9).

A 5 year old patient came to the clinic 6 months after onset of a tuberculosis of the hip. Two months later an incision was made over

the lateral aspect of the upper thigh with the idea of doing a subtrochanteric osteotomy as advised by Farkas in 1939. However the osteotomy was not performed because a wide spread deep abscess was encountered. This abscess became secondarily infected and the patient died of miliary tuberculosis 6 months after surgery.

From this study of 15 proved cases of tuberculosis of the hip in children the following observations have been made:

1. The treatment of tuberculosis of the hip must aim at fusion because only in rare exceptions is a stable, painless and movable hip joint obtained.

2. Surgery must be delayed until the general condition of the patient is satisfactory and

Fig. 5. a, Roentgenogram of the left hip of a 50 year old man who had had pain in the hip for months. There is advanced destruction of the femoral head and destruction of the acetabulum, but no bone troph. Pus as aspirated from the hip joint. The smear culture and guinea pig inoculation were positive for tuberculosis. The lungs were negative. The hip was immobilized in hip spica for 3 years. b, Roentgenogram taken 3 years later showing more destruction of the femoral head. The patient had very big abscess in the left thigh which was aspirated many times. There was fairly good range of motion in this hip which was only slightly painful. c, Roentgenogram taken 3 years later showing absence of the femoral head. The tuberculous abscess had disappeared and the general condition of the patient was excellent. d, Roentgenogram taken 7 years after onset of symptoms. The femoral head and acetabulum had been completely destroyed. The left hip was freely movable but unstable. The patient had no pain.

the roentgenograms show a sound reossification of the atrophic and of some of the previously destroyed bone. This 'healing reaction' appears usually from 1½ to 3 years after onset of hip symptoms, if a good general and local treatment is followed.

3. A warm widespread abscess is a contraindication for surgery. A cold, well local

ized abscess is not a contraindication. Lung tuberculosis was never a contraindication to surgery in children because the process healed long before the healing reaction occurred in the osteoarticular tuberculous lesion.

4. Extensive immobilization of the leg in hip spica casts should not be looked upon as an innocuous treatment and should not be pro-

longed any longer than necessary. Great atrophy shortening of the extremity and possible permanent damage to the epiphyseal plates about the knee and stiffening of the knee joint are frequent sequelae of prolonged immobilization (7).

5 As a rule, the optimum time for surgery is during the third year of the disease. If surgery is delayed beyond the third year the joint space may increase in width due to over growth of fibrous tissue and fibrocartilage which substitutes the destroyed joint cartilage.

6 Extra articular fusion will bring about prompt hip ankylosis only if there is contact between the bone of the femoral head and the bone of the acetabulum at the time of surgery.

7 Extra articular hip fusion alone will fail, or the ankylosis will be greatly delayed if there is abundant soft tissue in between the femoral head and the acetabulum at the time of surgery. It takes years for new bone trabeculae to penetrate into the avascular fibrocartilaginous tissue and cross the joint space in order to establish solid bony fusion. As much of the interposed fibrous tissue as possible will have to be removed at the time of surgery and the joint packed with bone chips if an arthrodesis is desired in a short time (3, 9).

8 A tuberculous hip joint is not completely immobilized even with a well fitted and extensive plaster cast. The potent adductor muscles tend to pull the thigh constantly into adduction (4). A bone graft applied over the outer aspect of a tuberculous hip joint will be submitted to distracting forces which will bring about atrophy of the graft and even its fracture. An extra articular bone graft over a tuberculous hip joint is usually incapable of stabilizing the hip if there is abundant soft tissue interposed between the femur and acetabulum (Fig. 8). A tuberculous hip is not safe until bone trabeculae cross the joint space.

In order to abolish the action of the adductors on the hip joint we have been performing a subtrochanteric osteotomy at the time of the arthrodesing operation of the hip. After the osteotomy the upper femoral fragment is under the almost exclusive action of the abductors. The denuded femoral head and acetabulum and the bone graft placed in the outer aspect of the joint are then submitted to pres-

sure stresses which stimulate new bone formation resulting in bony fusion (Fig. 12). Several weeks elapse before the osteotomy site becomes solid allowing the adductors to act anew over the hip joint area, but by then bony bridges have already started to form at the hip and the fusion proceeds unhampered. This procedure of combining the subtrochanteric osteotomy with the hip fusion has been used successfully by us in the arthrodesis of painful degenerative osteoarthritic hips and invariably the fusion time has been greatly shortened. Intertrochanteric osteotomy may be used in these cases to eliminate the action of the psoas over the upper fragment, but in tuberculosis a subtrochanteric osteotomy is safer. Metal fixation is unnecessary and in many instances it is harmful to the process of osteogenesis. It must never be employed in tuberculous lesions.

TUBERCULOSIS OF THE HIP JOINT IN ADULTS

Nine patients from 23 to 61 years of age with proved tuberculosis of the hip, were seen. There were 6 males and 3 females. Their hip tuberculosis started from 1 to 3 years prior to admission. Both hips were involved in 1 patient. In no instance was a para articular focus of osteitis seen in adults prior to the hip joint invasion.

The evolution of tuberculosis of the hip in adults varied more widely than in children and in many patients it was closely related to the evolution of their pulmonary tuberculosis. We found it convenient to classify the adult patients with bone tuberculosis into three groups.

Group A. Patients with cured or with minimal pulmonary tuberculosis who developed osteoarthritic tuberculosis of the hip of very slow onset with mild hip pain of intermittent character, slight limp, and slowly increasing stiffness of the hip joint. These patients had no tuberculous abscess formation but if one developed it was always small and noninfiltrative. The roentgenograms showed slow progressive thinning of the joint space and moderate destruction of the subchondral bone of the femoral head and acetabulum. The destructive hip process usually became arrested in 2 to 3 years.

There are in the files of this hospital 11 patients who very likely belonged to this group. In only 2 patients was it possible to prove by guinea pig inoculation the tuberculous nature of the lesion and only these 2 patients were included in our series. One was a 23 year old woman with a healed pulmonary tuberculosis who came to our clinic 3 years after onset of the hip symptoms. There was no tuberculous abscess and the roentgenogram showed an arrested hip lesion with very narrow joint space and minimal bone destruction (Fig. 13). The other patient was a 54 year old man with a fibrotic tuberculous lesion in the right apex of minimal extent. He was admitted to our service 10 months after onset of hip symptoms. A small cold abscess in Scarpa's triangle was found and the roentgenograms showed marked bone atrophy about the left hip and areas of subchondral bone destruction. An extra articular hip arthrodesis was performed shortly after admission in the first patient and one year after conservative treatment in the second patient. Both hip joints were solidly ankylosed 1 year after surgery.

Group B. Patients with active pulmonary tuberculosis who developed tuberculosis of the hip. Four of our patients belonged to this group: 2 males and 2 females of from 27 to 31 years of age. All these patients had more or less acute onset of sharp pain in the hip with marked limitation of motion. They soon developed large warm tuberculous abscesses. The roentgenograms showed rapid narrowing of the joint space, extreme bone atrophy, and in 2 patients one or two wedge shaped subchondral sequestra were seen (5). The roentgenograms taken in the consecutive months showed that the hip joint seemed to melt away in 3 patients while the other showed bone sclerosis 1 year after onset. All 4 patients died from 1 to 6 years after onset of hip tuberculosis with extensive lung cavities (Fig. 14).

At autopsy the hip joint was examined in 1 of these patients. Caseous material filled the cavity. The articular cartilage was absent, the synovia and joint capsule showed a great number of foci of caseous necrosis with minimal tubercle formations. There were areas of caseation necrosis in the bone marrow in the head of the femur and acetabulum. The

wedge-shaped sequestra proved to be formed by dead bone with primary caseous necrosis of all the marrow elements.

The orthopedic treatment for the patients of this group consisted only of immobilization of the leg with traction or hip spica.

Group C. Patients with very destructive osteoarticular tuberculosis, with big abscess collections and no or minimal pulmonary tuberculosis with surprisingly good general condition. Three patients, all males, from 37 to 63 years of age belonged to this group, one with bilateral hip tuberculosis and tuberculosis of the knee. These patients had no, or very low fever. The red blood count was almost normal however the sedimentation rate and the white blood count were elevated. The pain was moderate in character or sharp, aggravated by weight bearing. Large tuberculous abscesses collected in the middle, lateral or posterior aspect of the hip joint. Roentgenograms showed extensive destruction of the femoral head and not so much of the acetabulum. The bone destruction progressed for several years before the process became arrested. Two patients were treated conservatively and have been followed for 5 and 9 years. One is well and there are a few degrees of painless motion in the hip joint; the roentgenograms showed the femoral head reduced to one-third of its size. The process has been arrested now for 2 years and an arthrodesis operation has been advised but it has been refused by the patient. The other patient had the left femoral head completely destroyed before the tuberculosis became arrested 3 years ago (Fig. 15). He now has fairly good range of motion in this hip which is unstable. The other hip and one knee became involved 1 and 2 years after the onset of the symptoms in the left hip. His general condition has been good for the past 5 years. A 63 year old man was treated surgically by extra-articular fusion. An abscess was encountered around the hip joint which became infected and drained profusely until the patient died of cerebral thrombosis 3 months after surgery.

The treatment of tuberculosis of the hip in adults must vary according to the stage of the tuberculous process in each special case. The patients with hip lesions described for group

A may be treated by extra articular hip fusion as soon as the general and local tuberculous processes are under control usually from 2 to 3 years after the onset of the hip symptoms. Intra articular fusion in these involved hips is not absolutely necessary because the joint space is very narrow and is easily breached by bone trabeculae after the extra articular graft has become solid. The patients with tuberculous lesions as described in group B must be carefully studied before deciding upon any surgical procedure on the hip, because the hip tuberculosis is but a symptom of a spreading tuberculous process with no tendency to become arrested and surgery in these patients is definitely contraindicated. The patients of group C are better treated conservatively at first and surgery must be delayed until the destructive process becomes arrested. Resection of the upper femoral epiphysis may in the selected cases shorten the healing time. A hip fusion may be technically impossible to perform in many patients of this group when the process is arrested because of the extensive loss of bone substance. A Trumble or a Brittain operation may be the answer but we have had no experience with these procedures.

SUMMARY

The evolution and the results of conservative and operative treatments were studied in 31 proved cases of tuberculosis of the hip followed for a minimal period of 4 years.

The patients were divided into 3 groups. The first group comprises 7 patients all children who had a para articular focus of tuberculous osteitis. The roentgenographic and histological characteristics of the two different types of tuberculous osteitis were described. In the granulous osteitis the roentgenograms show a small area of uniform bone destruction whereas one or several small bone sequestra are seen in the area of destruction due to caseous osteitis. Both types of tuberculous osteitis have a tendency to heal under prolonged conservative treatment. However the hip joint in each of the 7 patients was invaded sooner or later by the tuberculous process.

The hip joint was very slowly destroyed when lesions of tuberculous granulation tis-

sue with no caseation predominated. On the other hand the involved hips were destroyed rapidly when lesions of caseation necrosis were widespread in the joint structures. The clinical symptoms in the last group of patients were of acute character whereas in the first group they were mild and chronic. Once the hip joint became involved it either fused spontaneously or a fusion operation had to be performed because of persistent pain and deformity. A Brittain operation performed in 1 patient 5 years after the onset of symptoms failed due to erosion of the graft by a tuberculous abscess.

It is proposed that the treatment of tuberculous osteitis close to the hip joint be directed toward obtaining an ankylosed joint as soon as the local process is quiescent and the general condition of the patient is favorable. No time should be wasted trying to heal the osteitic process by prolonged immobilization, because the hip joint becomes sooner or later involved in the great majority of patients.

The second group comprises 15 patients with tuberculous arthritis of the hip joint with onset during childhood. In 8 patients seen early after the onset of symptoms the tuberculous arthritis was probably of synovial origin. The symptoms and evolution of the tuberculosis of the hip in children were discussed both from the clinical and roentgenologic points of view. It was concluded that the treatment must aim at fusion because only in rare instances is a stable painless and movable joint obtained. Surgery must be delayed until the general condition of the patient is good and the roentgenograms show a sound reossification of the atrophic bone. This 'healing' reaction appeared usually from 1½ to 3 years after onset of hip symptoms if good general and local therapeutic measures were followed. The optimum time for surgery is, thus during the third year of the disease. If surgery is delayed beyond the third year the joint space may increase in width due to overgrowth of fibrous tissue. This overgrowth has to be removed at the time of surgery. The best results of hip fusion were obtained with the intra articular and extra articular methods combined. The author recommends a subtrochanteric osteotomy at the time of sur-

gery in order to abolish for a time the action of the adductors on the upper portion of the femur which submits the bone graft to distracting forces and thus to atrophy.

The third group comprises 9 patients of adult age with hip tuberculosis. Its evolution varied widely and in many patients it was closely related to the evolution of their pulmonary tuberculosis. Some patients had only minimal bone destruction with thinning of the joint space. Their general condition was good and responded well to an extra-articular arthrodesis. Other patients, who had active pulmonary tuberculosis, exhibited very extensive and fast destruction of the hip joint and died a few years after the onset of the hip involvement. Other patients had very destructive osteoarticular tuberculosis with abscesses but with good general condition. The process

lasted for a long time and when arrested the hip was very unstable.

PORTACAVAL ANASTOMOSIS

ARTHUR H. BLAKEMORE, M.D. New York, New York

THE portacaval shunt as an efficient means of ameliorating portal hypertension opens up a broad field of usefulness. It was heartening in our early cases to find that patients tolerated the operation amazingly well, also that despite the fact that a number were had risk patients only 5 in a series of 40 patients in whom portacaval shunts were completed failed to recover from the operation.

Although the portacaval shunt operation has been employed by us primarily to eliminate the threat of lethal hemorrhage in cases of portal hypertension, we have found that the concomitant relief of ascites when present has been effected.

A discussion of some of the causes of portal hypertension in terms of indications for the portacaval shunt follows.

Schistosomiasis We consider the portacaval shunt operation as the one great hope in cases of schistosomiasis of the liver. This is a disease that, in some part of the world, accounts for a good percentage of hospital admissions. From the natural history and pathology of the disease it is now well known that the patient dies from complications of portal hypertension rather than from damage to liver cells. From the point of view of liver function the cases are excellent operative risks. Portacaval shunt should protect them against lethal hemorrhage and assure the relief of ascites which in this disease is primarily the result of portal hypertension. We can report one case with an excellent postoperative result.

Chiari syndrome Our experience with Chiari syndrome (thrombosis of the hepatic veins) is limited to one case. The outstanding findings in this case was the presence of a very large liver, a spleen several times larger than normal, ascites and a moderately elevated

portal pressure upon measurement. Edema of the legs and a tendency to recurring pleural effusions was an additional unexplained finding in this case. The liver biopsy revealed extreme congestion with apparent widespread liver cell damage but strangely enough aside from a slight depression of serum albumin the liver function tests were but slightly if any deranged. A marked immediate improvement in the ascites followed the establishment of a splenorenal shunt in this case but, the persistence of some ascites marked leg edema and pleural fluid in the right chest constituted a problem. Finally with the institution of sodium lactate therapy, there was a marked response from diuresis and after the lapse of three weeks the edema had completely disappeared. (1) Now 1½ years since operation aside from a tendency to anemia, the patient's general condition has markedly improved. Her liver function studies are normal and the organ has returned to almost normal size. For the past 9 months she has worked as a secretary to the United Nations and states that by comparison her health is now robust.

Chiari syndrome is reputedly a serious condition from which patients do not recover. This patient after a 1½ year follow up is apparently recovering.

Banti's syndrome A common cause of portal hypertension in this country is Banti's syndrome. Patients so afflicted and showing esophageal varices or presenting a history of gastrointestinal bleeding are unequivocally candidates for the portacaval shunt. Those patients with Banti's syndrome who have essentially normal liver chemistry are unusually good operative risks for the portacaval shunt operation. Those having cirrhosis require special handling.

Cirrhosis of the liver and portal hypertension It has long been recognized that portal hypertension of varying degrees develops some time during the course of the disease in the common types of cirrhosis of the liver. The association of portal hypertension with the occurrence of

From the Department of Surgery, Presbyterian Hospital and College of Physicians and Surgeons, Columbia University, New York.

Presented in the Forum on Fundamental Surgical Problems before the Clinical Congress of the American College of Surgeons, New York, September 8-11, 1947.

hemorrhage and ascites in cirrhosis has like wise been long accepted as fact.

Whereas the fact remains that portal hypertension is the common basic cause of severe gastrointestinal hemorrhage in cirrhotics more recently prothrombin derangement as it affects blood clotting has been accepted as a co-factor in inciting or prolonging hemorrhage under certain conditions. Similarly the relationship of the blood proteins, particularly the albumin content as a factor in ascites is better understood.

Prothrombin derangement (deficiency) may be the result of two causes (1) failure to absorb vitamin K (2) inability of the liver to make adequate amounts of prothrombin. The former occurs in conditions effecting biliary obstruction in which the triad of jaundice acholic stools, and a high alkaline phosphatase are familiar. The latter occurs in serious decompensation of the liver.

Since progress has been made in recent years in the medical treatment particularly of Laennec's (portal) cirrhosis, it is pertinent to discuss its possible influence on the problem of hemorrhage.

Dr Arthur Patek (2) tells me that in his series of 124 treated patients the incidence of hematemesis was 33 per cent (42 cases). This compared with an incidence of 27.4 per cent reported by the same author (3) for a series of 386 untreated patients with cirrhosis indicates that the modern regimen has not reduced the incidence of hematemesis. Though one could not expect to affect favorably the portal hypertensive component in hemorrhage by a medical regimen it was hoped that improvement in the prothrombin component (as has certainly been demonstrated in many cases) would remove what would prove to be an important inciting factor and thus reflect a lower incidence of hematemesis.

The above comparative statistics, when coupled with the finding that ruptured esophageal varix was recorded as the cause of death in 100 patients (26 per cent) of 386 cases of cirrhosis (3) may be interpreted to indicate that portal hypertension rather than the prothrombin derangement component is the important factor in the cause of lethal hematemesis.

Whereas the incidence of hematemesis has not apparently been reduced following the introduction of the modern medical regimen for the treatment of Laennec's cirrhosis, the likelihood of a patient surviving an individual attack of hematemesis has improved. Credit for this may in large part, be due to more ready availability of transfusions through the development of blood banks. However we again refer to the results in Dr Patek's series of treated patients where we note, under optimum treatment conditions, that 22 of the 44 patients having hematemesis died. One half of the patients died within 1 year of the onset of their first hemorrhage.

A realistic appreciation of the figures given makes it imperative that those of us responsible for the care of patients with cirrhosis recognize our obligation to protect the patient from lethal hemorrhage.

Fortunately we now have adequate evidence that a portacaval anastomosis, either of the splenorenal or the portal vein to vena cava type will protect patients against the recurrence of severe gastrointestinal hemorrhage. The efficiency of the anastomosis in lowering the portal blood pressure thus preventing the occurrence of hemorrhage has been recorded and observed by us in patients again and again. The portacaval shunt operation has been accomplished by us forty times with an operative mortality of 12½ per cent. In view of these facts, we consider the procedure no longer an experimental operation but commend its consideration in cases of cirrhosis when patients have had one or more episodes of gastrointestinal hemorrhage—patients who when treated medically under the best of circumstances have only a 50 per cent chance of living.

Ascites. Although ascites regularly disappeared following the portacaval shunt operation when done in cirrhosis cases for the control of hemorrhage we do not consider ascites as a primary indication for the operation.

The outstanding achievement of the modern liver regimen in the treatment of Laennec's cirrhosis of the liver has been the relief of ascites. The relief of ascites occurs *pari passu* with improvement of liver function particularly in respect to a rise in the blood albumin.

Failure to clear ascites following a vigorous and prolonged treatment regimen is usually due either to failure to regain liver compensation in the presence of a too severely damaged liver or to the presence of excessive portal hypertension. The latter cause may be strongly suspected in patients whose blood albumin level is in excess of 3 per cent and essentially confirmed if roentgenograms demonstrate the presence of esophageal varices. We recommend portacaval shunt in this latter group of treatment failures for the following reasons: (1) The demonstration of esophageal varices in such cases is proof of the existence of a severe grade of portal hypertension which in itself constitutes a serious threat of sudden death from hemorrhage. (2) If this group of medical treatment failures are allowed to go on indefinitely with repeated paracenteses they eventually die of wasting ascites. (3) They are over all good operative risks. The liver is usually excellently compensated. The organ may be capable of maintaining an albumin blood level well in excess of 3 per cent were there not too much albumin loss through the removal of excessive amounts of ascitic fluid. Such patients are among our most grateful ones.

We hope in the near future to assemble our data in cirrhosis cases so that we may com-

pare the albumin blood level with ascites in the presence of different degrees of portal hypertension as measured at the operating table before and after the establishment of portacaval shunts. The frequently observed fact that ascites will appear in the average cirrhotic when the blood albumin approaches 3 per cent whereas tissue edema does not appear until a considerably lower level is reached may be taken as *prima facie* evidence that a portal hypertensive component is involved in the formation of ascites.

Posthepatitis cirrhosis. Posthepatitis cirrhosis is a disease seen all too frequently these days. When the disease has reached the stage of causing demonstrable varices with or without a history of bleeding if the liver function is yet reasonably good we recommend the establishment of a portacaval shunt. We have gathered the impression that when the disease has reached this stage the modern liver regimen affects little if any its downhill course and there is extreme likelihood of seriously persistent bleeding.

THE PHYSIOLOGY OF FECAL CONTINENCE

EUGENE A GASTON M.D., F.A.C.S Framingham, Massachusetts

STUDIES of the distal colon and anal sphincters in animals as reported by several investigators, have been fairly uniform in showing a functional relationship of one to the other. Similar studies in man while less numerous, have been mainly concerned with changes resulting from various nerve lesions. The purpose of this communication is to report the results of a study of the mechanism of fecal continence in normal adults. This mechanism is of particular importance to surgeons who within recent years have taken a renewed interest in sphincter preservation in resections of the rectum for cancer.

DEFINITION OF FECAL CONTINENCE

Fecal continence the ability to retain feces until its delivery is convenient is of two types colonic and sphincteric. Colonic continence depends on the plastic adaptation of the smooth muscle of the colon to the enlarging fecal mass. Its usefulness in the normal adult is evident in the practically constant finding by x ray and sigmoidoscopy of fecal material collected in the sigmoid above an empty rectum without the aid of an anatomically demonstrable sphincter at the rectosigmoid junction. It is this type of continence which is retained by the patient with well managed abdominal colostomy and its full utilization makes colostomy a bearable deformity. It is entirely under the control of the autonomic nervous system and may be responsible for some of the functional results reported by those who favor sphincter preservation.

Sphincteric continence implies the retention of bowel contents by sphincteric contraction when the plastic adaptation of the colon reaches an end and peristalsis begins. That

sphincteric continence is not a simple purse string effect but a complicated and highly integrated mechanism will be shown in the studies presented here.

THE SPHINCTERIC APPARATUS

While it is not the purpose of this communication to deal extensively with the anatomy of the sphincteric apparatus, several points which bear on the experimental findings to be reported should be clarified. The internal sphincter a collection of smooth muscle fibers surrounding upper portion of the anal canal is a continuation of the circular muscle of the distal part of the rectum. It is entirely under the control of the autonomic nervous system.

The external anal sphincter is composed of striated muscle under the control of the voluntary nervous system. It is variously described as consisting of two (9, 11, 15, 29, 35) or three (32) separate muscle bundles. With the anal canal closed the superficial portion of the external sphincter lies distal to the internal sphincter while the deeper portion partially overlaps it. With the anal canal dilated by the presence of a fecal mass or as in the experiments to be described by the presence of an obturator the two sphincters come to occupy a more truly internal and external position (11) although some overlap remains. These facts make it possible to secure graphs representing the function of each sphincter separately but only to a relative degree. A graph representing the function of one sphincter will necessarily have some components of the other superimposed on it. Sufficiently clear tracings can be obtained, however to indicate the function of each.

The external sphincter is made up of striated muscle which differs from that in other parts of the body in its reaction to denervation. Goltz and Ewald found that it remained reactive to electrical stimulation for long periods after the removal of the lumbar and sacral portions of the spinal cord in dogs. In animals

Fig. 1. Methods used for studying the mechanism of fecal continence. A, (method I) a simple manometric apparatus for recording the strength of voluntary sphincter contractions. B, (method II) for obtaining simultaneous readings of colonic and sphincteric activity (colo-sphincter-metrogram) later adapted to kymographic recording as in C, (method III). D, (method IV) for recording the effects of rectal stimulation on the anal sphincters. E, (method V) similar to D except that the activity of the internal and external sphincters are recorded independently and simultaneously.

poisoned with curare von Frankl Hochwart and Froelich found the external sphincter to react to stimulation long after other skeletal muscles had ceased to react, findings which have been only partially substantiated by the more recent work of Learmonth and Markowitz (27). Arloing and Chantre showed that there were no microscopic changes in the external sphincter 11 months after destruction of its nerve supply. Because of these findings the external sphincter 'has been conceived to possess nerve centers similar to those of the myenteric plexus of Auerbach' (24), a point that has been recently confirmed microscopically by Reuther.

The part played by the levator ani muscles in the maintenance of sphincteric continence is difficult to evaluate. They have been described both as dilators of the anal canal and as having a sphincteric function (32-34). Since these muscles have fibers running both radially and parallel to the anal canal it is probable both views are at least partially correct.

METHODS OF STUDY AND RESULTS

Method I

The first method of study consisted of a simple apparatus for measuring the strength of the voluntary contraction of the external anal sphincter. A cylinder of light rubber was fastened between the ends of an obturator 1 inch in diameter. The obturator was connected by heavy small bore rubber tubing to a blood pressure aneroid (Fig. 1 A). The obturator was inserted with the soft rubber cylinder encased by the anal canal. After the initial irritability of the sphincter caused by the insertion had subsided and the pressure due to the basic tonus noted, the patient was requested to close the sphincter with all possible force. The difference between the basic tonus and the greatest force exerted by the sphincter was used as an index of the strength of the voluntary sphincter. Table I shows the net increase of tonus during voluntary contraction of the anal sphincter in the 41 normal subjects examined by this method. These tests indicated

TABLE I—MAXIMUM FORCE EXERTED ABOVE BASIC TONUS DURING VOLUNTARY SPHINCTERIC CONTRACTION IN CONTINENT SUBJECTS

Min. mercury	No. cases	Percent
to 40 mm.		9
40 to 60	3	3.7
60 to 70		3.7
70 to 80	1	
80 to 90		1
90 to 100	3	7.3
over 100		1
Total	4	100

that the force exerted by the contracting sphincter could be maintained for only a very short time and furthermore that the strength of the voluntary sphincter contraction bore no apparent relation to sphincteric continence. Thus the maximum force of contraction varied from 9 millimeters of mercury in a 72 year old woman to 240 millimeters of mercury in a 45 year old man yet both had perfect sphincteric control of gas and feces.

Methods II and III

These observations led to efforts to adapt the colonmetrogram described by White Veriot and Ehrenthell to the solution of this problem. A second somewhat smaller obturator covered by a cylinder of soft rubber was constructed. The air space thus enclosed was connected to a blood pressure aneroid which was again used to indicate the pressure exerted by the contracting sphincter. The hollow center of the obturator was connected with a reservoir bottle containing water at approximately body temperature by means of which an enema could be given. A vertical glass manometer with the zero point at the level of the anus was connected between the obturator and the reservoir. Increments of 100 cubic centimeters or 200 cubic centimeters of water were allowed to run into the colon at a constant rate of approximately 100 cubic centimeters per minute after which the tube leading from the reservoir bottle was clamped and pressure readings on both manometers made (Fig. 1 B). The rapid fluctuations of colon and sphincter pressures made it impossible to

secure accurate simultaneous readings, and the method was therefore adapted to kymographic recording (Fig. 1 C). With the kymographic method the fall-away bellows, tubing and connecting tubes were filled with water to obviate errors that would otherwise occur from the compressibility of long columns of air. Electric recording (30) was found to be safe, clean and to require a minimum of friction between the writing point and the drum.

The kymographically recorded combined colonmetrogram and sphinctermetrogram (colo-sphincter-metrogram) was obtained on 1 normal adults. Measurements of the kymographic tracings were used to construct summary charts of which Figure 2 is an example. The lower line marked "A," is that of a normal colonmetrogram as described by White and associates. That is the lowest colonic pressure recorded between increments of injected water was used to construct the base line. The vertical dotted lines extending upward from the base line indicate the maximum pressure recorded in this interval between injections, and represent the efforts of the colon to empty itself by peristalsis. The central shaded area marked "B" represents the activity of the colon during the injection of each increment. The pressure of the fluid injection (height of fluid in reservoir) was kept at a constant level (30 cm. in Fig. 2). As soon as each injection was started the needle recording colonic pressure immediately jumped to a point indicating a pressure of from 30 to 40 centimeters of water. This was followed by waves of increased pressure indicating colonic contractions which tended to resist the injection of each increment. These waves of colon resistance were usually accompanied by an increased desire to empty the colon. The subjective limit of tolerance to colon filling by retrograde injection is usually about 2000 cubic centimeters. It was noted that up to a volume of 600 or 800 cubic centimeters the injection of each increment was accompanied by a subjective desire to defecate and at the same time by evidence of peristaltic activity in resisting the injection. In about the middle third of the enema, that is from 600 or 800 to 1200 or 1400 cubic centimeters each increment was attended with little or no peristaltic activity in resisting the

Fig. 2 The colo-sphincto-metrogram in a normal adult. A Shows the activity of the colon in centimeters of water pressure following the injection of 200 cubic centimeter increments of water per anum. B, Shows the activity of the colon during the injections, and C, the activity of the sphincter during the injections.

injection while during the injection of the last increments peristalsis again became active.

The activity of the sphincteric mechanism during the injection of each increment is indicated in the shaded area marked 'C' which is bounded by points indicating the lowest and highest sphincter pressures recorded during each injection. The similarity of sphincter activity and colon activity during the injection is evident. Thus during the first third of the enema both the colon and sphincter are quite active. This activity diminishes during the middle third but increases again in the latter part of the enema. This correlation of sphincteric activity to changes in colonic pressure is also illustrated in Figure 3, made after the colon had been filled to the limit of toleration. The waves of increased colonic pressure (C.P.) corresponding to peristaltic waves are associated with simultaneous increases of sphincter tone (S.P.). This correlation indicates that the sphincter responds by closing the anal canal only as the necessity for resistance to the propulsive peristaltic activity of the colon becomes necessary.

The necessity for this close correlation between peristaltic and sphincteric activity is evident from a study of the fatigue curves produced by voluntary sphincter contraction. These curves were obtained by placing the obturator across the entire anal canal so that the resultant of all components of the sphincteric apparatus was recorded. After the sphincteric activity resulting from the insertion of the obturator had subsided the patient was requested to contract the sphincter with all possible force and for as long a time as possible. Figure 4 illustrates typical fatigue curves. The initial contraction brought a rapid rise of sphincter pressure of but momentary duration and was followed by an irregular but progressive fall to the base line. Figure 4 A represents two separate voluntary sphincter contractions. At X in Figure 4 B the patient was urged to continue the contraction with all possible vigor and this encouragement resulted in some increased activity followed by a fall of pressure which paralleled that following the initial effort. Table II shows the maximum pressure exerted by the

Fig. 3. Colon pressure, C.P. and sphincter pressure, S.P. recorded simultaneously after the colon had been filled with water to the limit of toleration. Time line equals 30 seconds.

Fig. 4. Fatigue curves of voluntary sphincter contractions. Time line equals 30 seconds. Pressure scales in centimeters of water.

voluntarily contracted anus as well as the time during which there was any sphincteric activity however slight. An average maximum contraction of 44 centimeters of water pressure and an average duration of 52 seconds gives some indication of the fatigue curve of the normal voluntary sphincter. Introspection confirms the rapidity with which the voluntarily contracted sphincter fatigues and emphasizes again the necessity for correlation of sphincter tone to bowel activity in the maintenance of sphincteric continence.

Method IV

In an effort to evaluate the effects of local stimulation of the lower sigmoid colon and rectum on the sphincteric apparatus as well as to differentiate the functions of the internal

and external sphincters, the apparatus diagrammed in Figure 1, D was constructed. This consisted of a rubber balloon cemented to a graduated urethral catheter. The balloon was introduced into the sigmoid with the aid of a sigmoidoscope or into the rectum by digital manipulation. The end of the catheter was connected by a glass "T" tube to a 50 cubic centimeter syringe and a recording tambour. The balloon was distended with water by means of the syringe and pressure changes during and after filling were recorded kymographically. A small metal obturator was covered with a pliable rubber cylinder. The enclosed space was connected to a recording tambour and the system filled with water. By placing the obturator across the entire anal canal the combined activity of both sphincters was recorded while by moving the obturator further in or pulling it partially out of the anal canal fairly pure recordings of the pressure exerted by the internal or external sphincter could be obtained. The small catheter traversing the anal canal beside the obturator did not materially affect the recording of changes of sphincter tone.

The sensation resulting from distention of the balloon in various portions of the sigmoid and rectum was found to conform to the findings of Hertz. Distention of the balloon with 100 to 200 cubic centimeters of water when placed above the rectosigmoid junction (18 to 22 cm. above the anus) caused a pressure sensation which was referred to the lower abdo-

Fig. 5. The response of A, the internal sphincter B the external sphincter and C, both sphincters to the stimulus of a distended balloon placed in the rectum 10 centimeters above the anus. Arrows pointing upward indicate 50 cubic centimeter increments of filling. Downward arrows indicate 50 cubic centimeter decrements of emptying.

men usually in the midline but at times in the left lower quadrant. Similar distention of the balloon placed just below the rectosigmoid junction (15 cm. above the anus) gave rise to a desire to defecate which was localized in the sacral and posterior perineal regions. As the balloon was moved closer to the anus the same amount of distention caused progressively increasing sacral or perineal sensations. It is probably a matter of practical importance that the anal reflexes (to be described) which result from stimulating the rectum by distention of the balloon similarly vary in intensity according to the area of application of the stimulus. Thus with the balloon in the sigmoid little or no reflex activity results. The responses progressively increase as the stimulating balloon is placed closer to the anus.

Since the anal reflexes occurring in response to distention of the balloon varied with its location, all tests were carried out with the center of the balloon at a constant level of 10 centimeters above the anus. Contrary to the findings of Garry (18) sufficient distention of the balloon was found to be an adequate stimulus for the production of the rectoanal reflexes. After numerous trials it was found that filling the balloon to 250 cubic centimeters by means of five increments of 50 cubic centimeters each gave responses that were

consistent in different individuals and in different tests on the same individual. The tests were most satisfactory when done within a few hours after a normal evacuation.

Results The response of the internal sphincter to the stimulus of a distended balloon in the rectum was obtained by moving the obturator into the anus until only its proximal half was recording while its distal half protruded into the cavity of the rectum. When the obturator was placed across the entire anal canal, the kymographic tracing consisted of an irregular line with many sharp peaks and valleys representing minor but very rapid changes in muscle tone changes characteristic of striated muscle. As the obturator was inserted further there was frequently an abrupt change in the character of the tracing which showed fewer and much slower changes in tone, giving rounded curves characteristic of smooth muscle contractions. Occasional sharp peaks of striated muscle contraction were noted at times indicating partial overlapping of the internal sphincter by the external.

By careful attention to details it is possible to secure a response characteristic of the internal sphincter in nearly all normal adults. The characteristic internal sphincter response is shown in Figure 5 A. With the first increment of 50 cubic centimeters there may or

may not be a change of sphincter tone. Invariably with the second and succeeding increments following a short latent period, there is a rapid but smooth fall of sphincter tone represented by a dip of greater or lesser magnitude in the graph line. After the first such fall the tonus usually returns promptly to its former level but with each succeeding increment the tonus fails to return to its former level and after five or more increments the tonus is invariably appreciably lower than it was when the test was started. Since the external sphincter overlaps the internal and since as will be shown the external sphincter tonus is rising while the internal is falling with the last increments of the test there are frequently superimposed sharp momentary rises of pressure (*e* in Fig 5 A).

On withdrawal of 50 cubic centimeters from the distended balloon there is a prompt rise of internal sphincter tonus which at times momentarily exceeds the initial tonus, but returns to the initial level after about 1 minute. The second withdrawal may be accompanied by a similar response but succeeding withdrawals are usually not accompanied by significant changes in internal sphincter tonus.

The characteristic response of the external sphincter is shown in Figure 5 B. This is obtained by withdrawing the obturator until its proximal half protrudes beyond the anal verge while its distal half is gripped by the external sphincter. It will be noted that the graph line is characteristically different from that of the internal sphincter, the line being roughly irregular with numerous sharp peaks and valleys representing the rapid change of tonus characteristic of striated muscle.

With the first two increments there is a slight but definite rise of sphincter tonus. With the third, fourth, and fifth increments there are sharp rises of sphincter tonus which return to the preinjection level soon after the injections are completed.

This contraction response of the external anal sphincter was always obtained when the patient was instructed to make voluntary efforts at fecal retention as the subjective urge to defecate increased with each succeeding increment. When the patient was instructed to relax and not consciously resist the urge to

defecate, the response was frequently but not invariably obtained. Co-operation in this matter was difficult to evaluate. Even when the contraction response was not obtained there was no fall of external sphincter tonus such as was seen with the internal sphincter.

The combined response of both sphincters. With the above background concerning the independent action of the internal and external sphincters it is evident that in individuals willing fecal retention, the stimulus of a rapidly distended balloon in the rectum will cause changes in the tonus of the entire sphincteric mechanism which are the resultant of two forces: dilatation of the internal sphincter and contraction of the external sphincter. With the obturator placed across the entire anal canal the graph of sphincter pressure shows changes characteristic of either sphincter depending on which is dominant and, most commonly the changes characteristic of both sphincters can be discerned. In the latter instance the first few increments are frequently associated with a fall of sphincter pressure characteristic of the internal sphincter. As the balloon enlarges with succeeding increments and the urge to defecate reaches the level of consciousness and then becomes imperative, the character of the response changes to that of the external sphincter (Fig 5 C). It is of some interest that the internal sphincter response is nearly always obtained with the first increments of filling, often when the patient has no conscious awareness of a rectal sensation while the external sphincter response is often not obtained until rectal sensation is present. In some individuals the external sphincter is dominant throughout the test as in Figure 6 A while in others the early increments cause no change in pressure probably because the effects of the two sphincters cancel each other while the later increments show an external sphincter dominance (Fig 6 B).

Denny Brown and Robertson have shown in human beings that the internal sphincter reflex returns after the period of the spinal shock has passed not only when the lumbar and thoracic portions of the spinal cord have been transected, but also following complete destruction of the sacral cord. Figures 6, C and 6 D are the responses obtained in an 18

Fig. 6. A and B. The response of the entire sphincteric apparatus to the distention of a balloon in the rectum, 20 centimeters above the anus, in normal individuals. C, The response of the entire sphincteric apparatus to filling and emptying of a balloon in the rectum 20 centimeters above the anus in a patient with transection of the spinal cord. D. Same as C but with the obturator placed across only the external sphincter. In all graphs arrows pointing upward indicate 50 cubic centimeter increments of filling of the balloon. Downward arrows indicate 50 cubic centimeter decrements of emptying.

year old female who suffered a complete transection of the spinal cord from a compression fracture of the eighth thoracic vertebra 14 months before the tests were done. With the obturator across the entire anal canal (Fig. 6 C) the response is similar to the internal sphincter response of a normal individual. With the obturator across only the external sphincter (Fig. 6 D) the response is still that of the internal sphincter although of lessened magnitude because there is less fluid displacement from the obturator which is now being compressed over only half of its surface. The internal sphincter response in this patient confirms the findings of Denny Brown and Robertson in patients with transection of the spinal cord. With transection of the spinal cord the normal internal sphincter response together with the absence of an external sphincter response indicates that (1) cerebral connections are necessary for the execution of the external sphincter reflex although whether these connections must be made at the conscious level is not clear and (2) the internal sphincter response is independent of cerebral connections.

Method V

Proof that the curves described above represent respectively the function of the internal and external sphincters is seen in the results of experiments done with the apparatus shown in Figure 1. E. With this method tests were conducted in exactly the same fashion as described for method IV except that a metal septum was fixed in the middle of the obturator dividing it into distal and proximal compartments. Each compartment was connected for independent kymographic recording. With the metal septum placed at about the midpoint of the anal canal it was possible to record simultaneously the separate responses of the internal and external sphincters.

Figure 7 illustrates the effects of stimulation of the rectum on each of the sphincters recorded simultaneously. With each increment of filling of the balloon there is a rise of external sphincter pressure which falls to the base line soon after the injection is completed. As the balloon becomes more distended and conscious rectal sensation (which in this instance started at 80 c.c.) becomes more marked, the elevation of external sphincter pressure with

Fig. 7 The responses of A, the external sphincter and B, the internal sphincter resulting from filling and emptying a balloon placed in the rectum centimeters above the anus in normal individual. Line C shows 50 cubic centimeter increments of filling (i to j'' inclusive) followed by similar decimeters of emptying (j'' to j''' inclusive)

each succeeding increment is higher and lasts somewhat longer. No constant effect on the external sphincter is noted with emptying of the balloon. At the same time that the external sphincter pressure is rising the internal sphincter pressure is falling. Following the first increase of balloon volume the internal sphincter pressure returns promptly to its pre-injection level. Following the second and succeeding increments, however it does not return to the pre-injection level so that there is a progressive fall. With each reduction of volume of the balloon there is a rise of internal sphincter pressure which after the balloon is empty regains its original level.

Voluntary increase of rectal pressure as by straining to evacuate causes a fall of internal sphincter pressure similar to that accompanying distention of the balloon. Usually such an effort is accompanied by a rise of external sphincter pressure as shown at b in Figure 8 A. It is difficult to secure satisfactory co-operation of the patient in voluntary straining to defecate because of fear of embarrassment and this almost certainly accounts for the rise of external sphincter pressure noted under these circumstances. Figure 8 B b a tracing made with the single obturator across both sphincters, shows relaxation of the entire sphincter mechanism on straining to defecate. As the pressure falls, small jerky waves of contraction characteristic of the external sphincter are noted. During reflex increases of intra-abdominal pressure such as during coughing or sneezing the external sphincter contracts with such speed and vigor that no internal sphinc-

ter relaxation is recorded (a and a' in Figures 8 A and 8 B)

DISCUSSION

The findings described here indicate that in normal individuals anal continence is the result of a fine co-ordination between the rectum and the external anal sphincter. This co-ordination is mediated through reflexes involving both the autonomic and somatic nervous systems and initiated by impulses which arise in the wall of the rectum. The receptor mechanism may lie within the mucosa of the rectum, since the reflexes are abolished by the application of cocaine to the rectal mucosa (18), but more likely lies within the muscular wall, a point that requires further elucidation. Since the rectoanal reflexes become progressively more active the more distally the rectal stimulus is applied it is probable that the receptor units, while present over entire length of rectum, increase in number from above downward and are most numerous in that part of the rectum which lies immediately above the anal canal.

Afferent fibers arising in the wall of the rectum probably normally communicate through the spinal cord with efferent fibers innervating the internal anal sphincter since its reflex is abolished during periods of spinal shock. This reflex arc is independent of cerebral centers since it is not abolished when the spinal cord is transected in the lower dorsal region. Since it eventually returns after destruction of the sacral cord in man (12) and following resection of the spinal cord in experimental animals

importance and will be made the subject of a future communication.

SUMMARY AND CONCLUSIONS

1 Fecal continence may be conveniently classified as

a. Colonic continence, which depends on the plastic adaptation of the colon to the enlarging fecal mass. This is retained by patients with abdominal colostomy, as well as by those in whom the sphincters have been preserved following resections of the rectum

b Sphincteric continence a term which indicates the active contraction of the anal sphincters which thereby resist the propulsive force of colonic peristalsis

2 Pertinent facts relative to the anatomy of the sphincteric apparatus are reviewed

3 Five methods designed for the study of the sphincteric apparatus are presented.

4 The results of a study of the physiology of the sphincteric apparatus by these methods indicate that

a. Stimulation of the rectum causes the internal sphincter to dilate and to thereby prepare the way for evacuation

b The internal sphincter plays no part in sphincteric continence. Only the external anal sphincter and rectum are concerned with sphincteric continence

c Sphincteric continence is not a simple pursestring effect. The actively contracted external anal sphincter rapidly becomes fatigued because of this its activity must be delicately correlated to colonic activity

d The correlation of sphincteric to colonic activity is mediated through a nervous reflex. The afferent fibers of this reflex arise in the wall of the rectum and communicate with efferent fibers terminating in the external sphincter. The connection between afferent and efferent fibers takes place at cerebral levels.

e The rectum itself must be considered an integral part of the sphincteric apparatus.

5 Sphincteric continence may be lost under the following circumstances

a. Complete division of the external sphincter

b Transection of the spinal cord

c. Surgical injury of the efferent fibers in the external sphincter (inferior hemorrhoidal nerves)

d Removal of the afferent fibers of the rectoanal reflex by resection of all of the rectum

SURGERY IN BLEEDING PEPTIC ULCER

Urgent Operation and the Principle of Exclusion

RICHARD WARREN M.D., F.A.C.S., and THOMAS H. LANMAN M.D., F.A.C.S.,
West Roxbury Massachusetts

THE purpose of this report is twofold first, to examine the need for surgery during the active bleeding stage of bleeding peptic ulcer and second if such a need is established to describe a program for handling these patients. The program has as its two main features urgent operation in selected cases and the exclusion of the ulcer when such an ulcer is technically difficult or hazardous to remove. These principles have been advocated by Finsterer (15) by Allen (3) by Gray and Sharpe by Arneline and Gilbert, and by others. By defining a program based on these principles and by illustrating it with individual case reports we hope to accomplish a further clarification of the fundamental issues involved.

During the year July 1, 1946 to June 30, 1947 219 patients with a diagnosis of peptic ulcer were discharged from the Veterans Hospital West Roxbury 54 of whom either entered with the symptoms of hemorrhage or developed it after admission. Our experience with these patients forms the basis of the report.

THE NEED FOR SURGERY IN BLEEDING ULCER

A study of the literature leads one to the conclusion that reports on the frequency of hemorrhage in peptic ulcer in order to be informative, must be qualified by descriptions not only of the severity of the hemorrhage considered but also of the total cases studied. Thus we find in the literature (2, 4, 18, 19, 26, 27, 29, 30) that among hospital admissions for ulcer hemorrhage of any degree is reported as ranging between 11 per cent and 40 per cent of the cases. The incidence in our series was 24.6 per cent. In this same group, massive hem-

orrhage (entailing anemia below 3,000,000 red blood cells per cu. mm.) was recorded in the literature as between 9 per cent and 18 per cent of cases, the incidence in our series being 13.2 per cent. Furthermore if one considers as Stolte did a group of patients other than those admitted to hospitals for example all patients in the population suffering from peptic ulcer one finds that the reported incidence of hemorrhage of any degree is 56 per cent.

To be significant then a reported mortality rate in bleeding ulcer cases must be qualified by clearly showing whether the group considered is made up of patients with hemorrhage of any degree or only those with massive hemorrhage. The wide range of mortality as reported in the literature (2, 9, 10, 15, 18, 19, 23, 25, 27, 29, 30) namely 3 per cent to 25 per cent, is largely explicable on this basis. In discussing surgical mortality it is vital to know not only the degree of hemorrhage but at what time during the course of bleeding the operation was undertaken. The varying mortality rates following surgery for bleeding peptic ulcer (1, 7, 15, 16, 17, 19, 23, 28) which range from 4.1 per cent to 42.8 per cent seem after careful scrutiny of the reports to be explicable solely on the varying degrees of exsanguination of the patients at the time of surgery.

The greater seriousness of massive hemorrhage from peptic ulcer in patients past middle life has been testified to by many. Reports in the literature state that between 20 per cent and 33.3 per cent of such patients will die and that of all deaths from hemorrhage in ulcer patients 95 per cent are in this older age group (2, 6, 23, 29).

In summary, it can be stated that approximately 50 per cent of peptic ulcers bleed to some degree during the patient's life, that 25 per cent of hospital admissions for peptic ulcer have bleeding as one of the admission symptoms and that approximately 10 per cent of

TABLE I.—TYPES OF OPERATION FOR BLEEDING ULCER

1. Posterior gastroenterostomy (Mikulicz)
 2. Posterior gastroenterostomy with ligature of the pylorus (Finsterer)
 3. Above procedures plus tamponade of the duodenum (Finsterer)
 4. Ligation of pancreaticoduodenal artery plus direct ligation of the ulcer (Allen)
 5. Excision of ulcer (Finsterer, Heuer)
 6. Exclusion operation (Devine, Finsterer, Gray and Sharpe, Allen)
- Subtotal gastric resection with excision or exclusion of the ulcer (Finsterer, Allen, Walters and Cleveland, Heuer)

all such admissions have massive hemorrhage. The mortality in all patients who are admitted for massive hemorrhage and treated by conservative methods is between 5 per cent and 10 per cent. In the older patients this figure may rise as high as 33.3 per cent. The mortality following surgery for bleeding ulcer may be below 5 per cent if patients operated upon at an elective time are included in the group but it has approached 50 per cent if one considers only those in a state of exsanguination and on whom surgery followed a prolonged and unsuccessful attempt at conservative management.

Under current methods of conservative treatment therefore one or two of every 20 patients admitted with massive hemorrhage from peptic ulcer will die. These patients are almost invariably in the older age group. It is they who establish a need for surgery in the treatment of bleeding peptic ulcer.

SURGICAL MANAGEMENT

A. Urgent operation. Since the mortality following surgery seems to be directly dependent upon the degree of exsanguination of the patient at the time of operation we have found it useful to separate operations done during different phases of exsanguination into three categories namely emergency, urgent, and elective. Emergency operations are those undertaken to stop hemorrhage in patients already in a state of shock in whom it has not been possible before operation to restore the blood volume or to correct, even partially, the acute anemia. Urgent operations are those performed to stop hemorrhage or to prevent recurrence of hemorrhage in patients who are

not in shock but in whom it has not been possible preoperatively to correct completely the anemia, the hypoproteinemia, or other factors such as upper respiratory infection, which may increase the operative risk. Elective operations are those performed on the patient of the ulcer after a considerable period of time has elapsed following the cessation of hemorrhage and in whom all the aforementioned deficiencies have been corrected.

Although some disagree (29, 30) it is the testimony of many observers (2, 8, 13, 14) that whereas massive hemorrhage which is indistinguishable from that in the early course of a fatal hemorrhage can arise from a small anterior wall gastric or duodenal ulcer the patients who die are those whose bleeding comes from ulcers which are eroding large arteries namely the pancreaticoduodenal and the right and left gastric arteries. Apart from demonstrating by roentgenogram that the ulcer lies in one of these areas and from taking into account the patient's age there is as yet no satisfactory method for deciding early in the course of the hemorrhage which patients will stop bleeding on conservative treatment. Since the use of an unduly prolonged trial of conservative therapy in making this decision will occasionally leave one with an exsanguinated patient upon whom one is forced to perform an emergency operation and with it accept only a 60 to 70 per cent chance of survival we have used earlier operation on a larger group in order to avoid this eventuality. Specifically we have advocated and performed the urgent operation for any patient over 45 years of age who continues to bleed massively from a proved peptic ulcer for more than 24 hours after admission or who having bled massively and stopped has shortly thereafter bled again.

B. Exclusion of the ulcer. The types of operation that have been advocated for bleeding ulcer are outlined in Table I. We have adopted as the ideal operative program a subtotal gastrectomy which entails removal of the lower two-thirds of the stomach including the pylorus followed by the re-establishment of bowel continuity by an end-to-side gastrojejunostomy. Removal of the ulcer may be safely accomplished as part of this procedure

if it is on the anterior surface of the stomach or duodenum. If the ulcer is on the posterior surface and is penetrating the pancreas or gastrobepatic ligament, however, we have considered the additional procedure of removal of the ulcer too formidable to undertake in these patients. In such circumstances therefore we have performed exclusion of the ulcer on the assumption that diversion of the gastrointestinal stream from its surface will avoid repeated digestion of the normal clot which forms within it.

There is evidence to show that even in the most severe bleeding from ulcer clotting will occur intermittently during its course but that this clot will be redigested by the gastric juice passing over it. First in fatal cases death does not occur until some time has passed. Allen found that in 20 fatal cases the average length of time from onset to death was 16 days. Chiesman reports that in 46 fatal cases none died within the first 48 hours. Thorstad found the average period in the hospital of all fatal cases to be 6 to 10 days. It is difficult to believe that uninterrupted continuous bleeding would have allowed patients to survive for these periods even with the aid of multiple transfusions. Second Finsterer reports in a large group of cases that the ulcer is usually not bleeding at the time surgery is undertaken but contains a soft clot in a vessel in the ulcer base. On the basis of this evidence we have proceeded on the assumption that exclusion of the ulcer from the action of the gastric juice is the one most important factor in preventing recurrence of hemorrhage.

Of our 54 patients who had bleeding from peptic ulcer 29 were considered to have a massive hemorrhage (red blood corpuscles below 3,000,000 per cu. mm.) Twenty of these 29 bled rapidly and seriously. Of this 20 10 continued to bleed or the bleeding having stopped, bled again. Of these 10 4 were over 45 years of age and having proved peptic ulcers received urgent operation. Their postoperative courses were satisfactory and there were no deaths. Of the 4 patients operated upon 1 had a small anterior wall duodenal ulcer, bleeding from which probably would not have been fatal. A subtotal gastric resection with excision of the duodenal ulcer was performed. A

simultaneous cholecystectomy and choledochostomy was also carried out because of the incidental discovery of gall stones. In the other 3 cases the ulcers were of the posterior penetrating variety and had eroded large arteries. Each ulcer was treated by exclusion. Since they presented three different problems in technical management illustrative of the three types of situation which call for exclusion rather than excision they are reported in detail.

CASE REPORTS

CASE 1 The patient was a male steam fitter aged 53 years who entered the hospital on May 29, 1947 because of melena of 1 week's duration and because of a fainting attack on the morning of admission.

Past history disclosed that the patient had had a diagnosis of peptic ulcer made in 1934 at another hospital following admission there for abdominal pain. At a second hospital admission in 1940 and following another x-ray examination of his stomach he was told that he had a duodenal ulcer. Since that time he had had symptoms typical of ulcer and 3 weeks prior to the present admission he had an exacerbation of his epigastric pain which continued steadily until admission.

On admission the patient was extremely pallid and was mentally confused so that an adequate history was difficult to obtain. The blood pressure was 120/80, the pulse 110, and the temperature 101.4 degrees. The physical examination was otherwise negative.

The red blood cells were 2,200,000 per cubic millimeter and the hemoglobin 8.4 grams. Urine sediment showed 7 white blood cells per high power field and there were 4 to 6 granular casts per low power field.

The patient was placed on a diet consisting of two-hourly feedings of milk and cream and was given dilaudid and sodium linlinal for sedation and during the succeeding 2 weeks he received 4,000 cubic centimeters of blood intravenously. He continued to pass tarry stools all showing a plus test for occult blood. The red blood count and hemoglobin fell during the first 3 days to 1,900,000 and 5.4 grams respectively but 6 days later had risen to 3,400,000 red blood cells and 7.9 grams of hemoglobin when they again fell to 3,400,000 red blood cells and 7.9 grams of hemoglobin. Gastrointestinal x-ray examination performed on May 30, the day after admission showed a large diverticulum 5 by 6 centimeters on the lesser curvature of the stomach, a thickening of the gastric rugae with folds radiating toward the diverticulum, a deformed duodenum with a large diverticulum projecting from its greater curvature side, and a third diverticulum projecting to the left of the descending portion of the duodenum.

Because of the patient's continued or persistent bleeding he was operated upon on June 14, 15 days

Fig. 1. Diagram of the operative procedure in Case 1. A standard subtotal gastric resection was performed removing the distal three fourths of the stomach including the pylorus. The gastric ulcer is shown remaining *in situ* against the pancreas but excluded from the gastrointestinal tract.

after admission. A subtotal gastrectomy was performed removing the lower three fourths of the stomach including the pylorus. A Hincaster type of anastomosis was effected anterior to the colon. An ulcer 2.5 by 5 centimeters was found to be eroding the upper edge of the pancreas and the left gastric artery. This ulcer was not actively bleeding at the time and it was left *in situ* but excluded from the gastrointestinal tract (Fig. 1). It was apparently the cause of the diverticulum seen in the roentgenogram. The duodenum, contrary to the diagnosis made by means of the x-ray, seemed normal.

The patient's convalescence was smooth. He received 500 cubic centimeters of blood on the day following surgery and another 500 cubic centimeters 11 days later. The red blood cells were 4,300,000 per cubic millimeter 14 days after operation with 12.5 grams of hemoglobin. The first stool passed after operation was of a tarry nature but subsequent stools were brown and on the eleventh postoperative day the guaiac test for occult blood had changed from a plus to a plus.

The case is that of a large gastric ulcer penetrating the pancreas which bled persistently and massively for a period of 3 weeks. Diagnosis by means of the x-ray had been made during the episode of bleeding. Urgent surgery was performed 15 days after admission. A standard subtotal gastric resection was performed removing the lower three fourths of the stomach including the pylorus. The ulcer was left *in situ* in the pancreas but excluded from the gastrointestinal tract.

CASE 2. A 55 year old male automobile mechanic entered the hospital on December 10, 1946, because of a 3 day story of tarry stools, weakness and weakness. Three days before admission the patient began to have severe epigastric pain. Two days before admission he was awakened in the morning by severe pain which was followed by syncope by the vomiting of considerable quantities of black material and by the involuntary passage of black stools. The patient was disoriented after recovering consciousness.

One year prior to entry the patient had passed tarry stools and had had a period of 5 days of "weakness." He had had a chronic cough for many years and was admittedly a heavy drinker. He said that he had had arthritis for 7 years.

He showed marked pallor but was mentally clear. The temperature was 98.6 degrees, the pulse 80, and the blood pressure 120/80. There was no tenderness in his midepigastrium.

The red blood cells were 2,500,000 per cubic millimeter with 7 grams of hemoglobin. Urine was normal, blood nonprotein nitrogen 41 milligrams per 100 cubic centimeter, and the blood glucose 67 milligrams per 100 cubic centimeters. The serum protein was 8.4 grams per 100 cubic centimeters.

The patient was placed on an ulcer diet with three hourly feedings and was given sodium laevulinate and atropine. On the day following admission his temperature rose to 101.8 degrees and his pulse to 120. He complained of more pain and vomited blood-stained material which was not bloody. A course of penicillin injections was started and his temperature subsided on the fourth hospital day although his pain continued. On the third fifth and sixth day in the hospital the patient had massive melena and on the sixth day he went into shock, the blood pressure

Fig. 2 Diagram of the operative procedure in Case 2. A standard subtotal gastric resection was performed removing the lower three fourths of the stomach including the pylorus. The duodenal ulcer is shown remaining *in situ* posteriorly within the duodenum immediately distal to the duodenal stump. It remains in the gastrointestinal tract but is excluded from the gastrointestinal stream.

falling to 80/60 and his pulse rising to 120 the hemoglobin this day being 7 grams. He had received 1 500 cubic centimeters of blood during the 6 days following admission. Because of this recurrent hemorrhage the patient had an emergency gastrointestinal x ray series on the fourth day in the hospital at which time a duodenal ulcer was visualized.

On the seventh day after admission urgent operation was performed. The patient was found to have a posterior wall duodenal ulcer about 1.5 centimeters in diameter and 2 centimeters distal to the pylorus. In the center of this ulcer was a hard cartilaginous nodule at the apex of which was an open blood vessel which was not bleeding. A subtotal gastrectomy was done a posterior Hofmeister type of gastroduodenostomy being used. The gastroduodenal segment was transected just distal to the pylorus and the duodenum turned in so that the turned in tuft of duodenum lay in the ulcer crater (Fig. 2). The patient received 1 000 cubic centimeters of blood on the day of operation.

Convalescence was smooth. The patient received 500 cubic centimeters of blood on the second post-operative day. By the tenth day the red blood cells were 3 700 000 and hemoglobin 12 grams. There was no external evidence of further bleeding.

The case is that of a large posterior wall duodenal ulcer which bled recurrently and massively for 10 days prior to surgery. The diagnosis was made by means of x ray examination carried out during the bleeding episode. Urgent operation was performed, the gastroduodenal segment being transected between the pylorus and the ulcer which was excluded and left *in situ* in the duodenum distal to the turned in duodenal stump.

CASE 3. A 49 year old male post office inspector entered the hospital on May 29 1947 because of progressive weakness over a period of 5 days associated with melena and hematemesis.

His illness started 2 weeks before admission when he began to have severe epigastric and left upper abdominal pain which was not relieved by food or antacids. Five days later this pain became more noticeable in the chest rising behind the sternum into the throat. At this time he first noticed tarry stools. Four days before admission he had hematemesis and had two more subsequently with continued tarry stools.

The patient had ulcer symptoms for 16 years and in 1938 an x ray examination showed a duodenal ulcer but there had been no previous hemorrhages and no symptoms of perforation or of pyloric obstruction had been present.

Physical examination showed extreme pallor of the skin restlessness deep sighing respiration and there was dried blood about the nostrils and mouth. Blood pressure was 90/50 and pulse rate 120.

Laboratory studies revealed a hemoglobin of 5 grams and a urine which was negative except for a 1 plus positive test for acetone and 5-10 white blood cells per high power field in the sediment. Blood leucocytes were 23 000 per cubic millimeter.

The patient was put on a milk and cream diet and phenobarbital and atropine. He received 1 000 cubic centimeters of blood on the day of admission and 1 500 cubic centimeters from the second to the fifth day. The pain in the epigastrium continued and was quite severe. He vomited a small amount of blood on one occasion. The red blood cells rose to 3 500 000 and the hemoglobin to 6.9 grams by the fifth day in the hospital when he vomited 300 cubic centimeters of coffee-ground material and 600 cubic centimeters more was removed from his stomach by aspiration. The red blood count fell again to 2 500 000 red cells.

Fig. 3. Diagram of the first operative procedure in Case 3. A subtotal gastric resection was performed removing the distal three fourths of the stomach including the pylorus in 1 stage. The first stage is shown here. The stomach is transected 8 centimeters proximal to the pylorus and the distal cut end closed in. The duodenal ulcer surrounded by a large inflammatory mass is shown excluded from the gastrointestinal stream as in Case 2.

On the sixth day an emergency gastrointestinal roentgenogram was taken which showed the large crater of an ulcer in the region of the pylorus.

On the sixth hospital day operation was performed. There was found an inflammatory mass 8 centimeters in diameter in the region of the pylorus. The first stage of a two stage subtotal gastrectomy was performed, the gastric antrum being transected 3 inches proximal to the pylorus and closed in. There was no evidence of fresh blood in the stomach, but visualization of the ulcer crater through the pylorus could not be obtained. The middle half of the stomach was resected and a posterior Hofmeister gastrojejunostomy performed (Fig. 3). During the morning prior to operation 1500 cubic centimeters of blood were given during and following operation.

Convalescence was satisfactory. The red blood cells on June 6, 1937, two days after operation were 4,500,000 per cubic millimeter and the hemoglobin 11.8 grams. The stools were positive for occult blood on the first few days after operation but on the twelfth postoperative day they were negative for occult blood. The patient was discharged on the seventeenth postoperative day.

He returned to the hospital on July 23, 1937, forty-nine days after the first stage operation and a second stage gastrectomy was performed 5 days later. At this operation the inflammatory mass had apparently completely subsided. The removal of the antrum, the pylorus and the scar of duodenal ulcer now about 3 centimeters in diameter with a turn in of the duodenum distal to the ulcer was easily performed. The convalescence was uneventful.

The case is that of a large posterior wall duodenal ulcer associated with a large inflam-

matory mass. The patient had had symptoms of severe ulcer activity for 3 weeks with recurrent massive hemorrhage for 12 days prior to surgery. Urgent first stage gastrectomy was performed excluding the ulcer but not excising it. Later a second stage gastrectomy with removal of the ulcer was carried out.

DISCUSSION

These 3 cases represent three types of situation that may arise when the ulcer is difficult to remove. In Case 1 the penetrating gastric ulcer the ulcer could be completely excluded from the intestinal tract although it was left *in situ* in the pancreas. In Case 2 the penetrating duodenal ulcer situated some distance from the pylorus the gastroduodenal segment could be transected between the pylorus and the ulcer which was left *in situ* in the duodenum. In Case 3 the penetrating duodenal ulcer which caused the large juxtapyloric inflammatory mass the gastroduodenal segment was transected proximal to the pylorus and at a later second stage the removal of the gastric antrum and the pylorus was done in the manner advocated by McKittrick. In Cases 2 and 3 although the ulcers were left *in situ* within the intestinal tract, they were effectively excluded from the intestinal stream and no further bleeding occurred.

We realize that early operation in these older patients which is advocated to forestall a fatal outcome in a minority of cases does subject to operation a larger number of patients whose bleeding might have stopped had conservative treatment been continued. We therefore feel that to justify the adoption of this more radical policy it must satisfy 5 criteria (1) it must stop active hemorrhage and prevent recurrent hemorrhage (2) it must entail the use of the simplest possible operative procedure (3) this operative procedure must give the patient as complete protection against recurrent or marginal ulcer as would a later elective operation (4) it must not submit to operation patients in whom there would be no indication for later resection assuming the hemorrhage could be successfully treated by conservative means (5) it must not result in a mortality rate higher than that expected for the elective surgery of peptic ulcer in a similar age group

We consider criterion 1 to be satisfied by the exclusion of the ulcer from the gastrointestinal stream criteria 2 and 3 by resorting to exclusion of the ulcer or the two stage operation under the indications outlined and 4 by the group selected most of whom being older patients with severe hemorrhage would be recommended for elective surgery at a later date supposing the hemorrhage to have been successfully treated by conservative means. Whether criterion 5 is fulfilled under this policy cannot be told until a large selected group of these patients is analyzed and comparable mortality rates determined. Our experience with these few cases has been most favorable and we believe justifies a continuance of the policy.¹

The credit for advocating the exclusion operation in selected cases of bleeding belongs to Finsterer to Gray and Sharpe and to Allen. We should mention here a point which needs further emphasis. If an exclusion operation has been performed which entails leaving any part of the gastric antrum *in situ* this remnant of the antrum should be removed at a later date in order to avoid a marginal ulcer. The high incidence of jejunal ulcer following gastric resections in which antral mucosa has

been left *in situ* has been recognized by many. The removal of the antrum at a second stage following the performance in selected cases of a first stage exclusion operation has been advocated by McKittrick. We feel with him that the term 'first stage gastrectomy' is in these cases preferable to 'exclusion operation'.

The credit for advocating early operation undoubtedly belongs to Finsterer who apparently operated on all massive bleeders within 48 hours after onset. We have considered our more rigid selection of cases however as preferable to his broader indications.

We have not adequately discussed the technique of management of patients who at operation are found to be actively bleeding from the ulcer bed. We feel that under a policy of urgent surgery for the older age group few such situations will arise. It is undisputed that when such an occasion arises an attack of some sort on the bleeding vessel must be made. Access to the ulcer bed is available directly in such situations as those illustrated by Case 1 and indirectly through the transected duodenal stump in such a condition as is illustrated by Case 2. In these cases by direct application to the ulcer of pressure or of hemostatic agents such as muscle fibrin foam or gelatin sponge the bleeding can readily be stopped. The situation is then identical with that in which the bleeding was not in progress when the abdomen was opened and exclusion of the ulcer can be performed. If active bleeding is in progress from the ulcer when the situation is as outlined in Case 3 one must decide at operation whether to rely on the exclusion procedure to permit the formation of a clot or whether a direct attack through an incision in the anterior face of the gastroduodenal segment is needed. It is our opinion that the latter will rarely be necessary. If it is undertaken however the technique of reconstructing the duodenum and antral remnant as described by Allen should be used.

SUMMARY AND CONCLUSIONS

The use of methods of nonsurgical treatment of massive bleeding from peptic ulcer which have been produced to date has always resulted in a small percentage of cases which

¹Since this group was studied 6 more patients have received urgent operation without mortality.

Fig. 3. Diagram of the first operative procedure in Case 3. A subtotal gastric resection was performed removing the distal three fourths of the stomach including the pylorus in 10 stages. The first stage is shown here. The stomach is transected 8 centimeters proximal to the pylorus and the distal cut end closed in. The duodenal ulcer surrounded by a large inflammatory mass is shown excluded from the gastrointestinal stream as in Case 2.

On the sixth day an emergency gastrointestinal roentgenogram was taken which showed the large crater of an ulcer in the region of the pylorus.

On the sixth hospital day operation was performed. There was found an inflammatory mass 8 centimeters in diameter in the region of the pylorus. The first stage of a two stage gastrectomy was performed the gastric antrum being transected 3 inches proximal to the pylorus and closed in. There was no evidence of fresh blood in the stomach, but visualization of the ulcer crater through the pylorus could not be obtained. The middle half of the stomach was resected and a posterior Hofmeister gastrojejunostomy performed (Fig. 3). During the morning prior to operation 1,500 cubic centimeters of blood were given during and following operation.

Convalescence was satisfactory. The red blood cells on June 6, 1937, two days after operation were 4,500,000 per cubic millimeter and the hemoglobin 18 grams. The stools were positive for occult blood on the first few days after operation but on the twelfth postoperative day they were negative for occult blood. The patient was discharged on the seventeenth postoperative day.

He returned to the hospital on July 23, 1937, forty-nine days after the first stage operation and a second stage gastrectomy was performed 3 days later. At this operation the inflammatory mass had apparently completely subsided. The removal of the antrum, the pylorus and the scar of duodenal ulcer now about 3 centimeters in diameter with a turn in of the duodenum distal to the ulcer was easily performed. The convalescence was uneventful.

The case is that of a large posterior wall duodenal ulcer associated with a large inflam-

matory mass. The patient had had symptoms of severe ulcer activity for 3 weeks with recurrent massive hemorrhage for 12 days prior to surgery. Urgent first stage gastrectomy was performed excluding the ulcer but not excising it. Later a second stage gastrectomy with removal of the ulcer was carried out.

DISCUSSION

These 3 cases represent three types of situation that may arise when the ulcer is difficult to remove. In Case 1 the penetrating gastric ulcer the ulcer could be completely excluded from the intestinal tract although it was left *in situ* in the pancreas. In Case 2 the penetrating duodenal ulcer situated some distance from the pylorus the gastroduodenal segment could be transected between the pylorus and the ulcer which was left *in situ* in the duodenum. In Case 3 the penetrating duodenal ulcer which caused the large juxta-pyloric inflammatory mass, the gastroduodenal segment was transected proximal to the pylorus and at a later second stage the removal of the gastric antrum and the pylorus was done in the manner advocated by McKitttrick. In Cases 2 and 3 although the ulcers were left *in situ* within the intestinal tract, they were effectively excluded from the intestinal stream and no further bleeding occurred.

ROUTINE USE OF OPERATIVE CHOLANGIOGRAPHY

PHILIP F PARTINGTON M.D., and MAURICE D SACHS M.D. Cleveland Ohio

THE need for additional diagnostic methods to improve the results in gall bladder surgery has long been acknowledged. In 1936 Lahey concluded that previous to 1926 he had left a stone in the common duct in one out of every ten patients subjected to a cholecystectomy. In an effort to decrease this high incidence Lahey increased common duct explorations to 44 per cent in a series of 2 000 cases with the discovery of calculi in 18 per cent of the last one third of this series (8). In view of the increased mortality and morbidity associated with choledochostomy it is easy to understand the reluctance of most surgeons to explore the common duct unnecessarily. Secondary operations are sufficiently formidable however to justify considerable effort to prevent them.

The possibility that careful study of diagnostic methods other than operative ones might improve results led Minzzi, Best, Hicken and others to the use of immediate or operative cholangiography (2, 6, 7, 11, 13, 14). In spite of the variety of contrast media and varying surgical and roentgenographic techniques used their results nevertheless showed the value of this procedure. Although these results were reported by Minzzi in 1931 and by Best and Hicken in 1936, operative cholangiography has not been generally adopted due chiefly to prolongation of operating time and difficulty in the interpretation of technically inferior films (20).

The purpose of this paper is to report our results with the routine use of operative cholangiography on all patients requiring gall bladder or common duct surgery during the past year 1946-1947. An attempt has been made to eliminate the causes for poor films and delay. The technique to be described has been

functioning to the satisfaction of the surgeon and the radiologist. It must be emphasized that not only interest but absolute co-operation must be maintained during the procedure. The slightest miscalculation on the part of any one of the team will nullify the entire examination or necessitate its repetition.

TECHNIQUE

The technique of operative cholangiography is simple and excellent films can be obtained routinely with attention to a few details. The procedure does not prolong the operation more than 5 to 10 minutes. The only special equipment necessary, a plywood tunnel can be fabricated quickly in any hospital utility shop.

The patient is placed on the operating table with a plywood tunnel beneath his abdomen and lower thorax without an intervening mattress. A pad of the same thickness as the tunnel covers the rest of the table. The tunnel should be large enough to permit easy passage of a cassette carrying a 14 by 17 inch x ray film and a grid. A 10 by 12 inch cassette and grid can be used just as effectively but requires more accurate centering. Use of the tunnel precludes the use of a gall bladder rest though this may be compensated for partially by means of folded towels. Drapes and wound towels are sewed in place to avoid the presence of metal towel clips in the roentgenogram.

The choice of incision is governed by the width of the costal angle. Paracostal or transverse incision allows the catheter containing the radiopaque substance to be brought in from the side without obscuring any of the underlying duct system. Following the opening of the abdomen, this biliary duct system is carefully inspected and the cystic duct at its junction with the common duct is dissected. A tie is placed on the cystic duct close to the gall bladder to prevent injection of radiopaque material into the gall bladder. If the gall bladder is filled with dye, it produces a dense shadow which may often overlie the sphincter of Oddi or some other part of the choledochus.

come to the surgeon because these medical measures have failed. In these cases, especially if there has been a prolonged trial of such a medical regimen the postoperative mortality is high.

Early urgent operation is, therefore advocated on all patients with massive hemorrhage from peptic ulcer who are over 45 years and in whom the hemorrhage persists after 48 hours following admission to the hospital or having stopped recommences.

Subtotal gastrectomy with removal of the lower two-thirds of the stomach including the pylorus, should be the surgical plan for these patients.

In those patients in whom the ulcer is technically difficult to remove a subtotal gastrectomy with exclusion but not removal of the ulcer is advocated. In patients with a large inflammatory mass involving the pylorus and duodenum a two stage subtotal gastrectomy as described by McKiltrick should be done.

Technical results were found to be directly dependent upon the team's experience with the procedure. The team consisted of a surgeon, radiologist, anesthesiologist, and technician. A number of different teams took part in the present study so that the results could not be expected to be as good as if one team had done the entire group.

Of the group of 30 cholangiograms, 17 cases (56%) were excellent, 10 cases (33%) were diagnostically adequate but had technical shortcomings, and 3 cases (10%) were failures. To account for the failures, in one instance the needle slipped out of the common duct and the diodrast was deposited as an indiscriminate mass in this region. In the second, due to uncertainty that the needle was in the common duct, it was withdrawn and reinserted. Diodrast leaked from the hole in the common duct at the site of the initial puncture and obscured the detail. The third case was a false positive in which two spherical negative densities were visualized near the junction of the cystic and common ducts. Subsequent common duct exploration and T-tube cholangiogram showed no calculus. The artifact was attributed to air bubbles. In increasing familiarity with the procedure and the difficulties involved, has greatly raised the percentage of diagnostic films during the past few months. Of the last 15 cholangiograms, 12 (80%) were excellent, 2 (13.3%) were diagnostically adequate, and 1 (6.7%) was a failure (Fig. 1).¹

Although the objective of operative cholangiograms as first used was the determination of the presence of common duct calculi, they have proved a diagnostic aid in other lesions involving the biliary duct system, such as tumors of the head of the pancreas, common duct or liver inflammation or spasm of the sphincter of Oddi, indirectly pancreatitis or hepatitis. The true anatomical picture of the extrahepatic and intrahepatic systems is well visualized (1-17). Following are representa-

¹Since this paper was presented for publication, an additional 30 patients have received routine operative cholangiography. There has been a marked improvement in the technical excellence of the films due largely to the adoption of the routine of a serial cholangiogram with 1 cubic centimeters of the contrast media injected each time. Eighty per cent of the films were excellent, 10 per cent diagnostic, and 10 per cent failures. It is of interest that the failures occurred with new residents not entirely familiar with the procedure.

Fig. 1. Normal operative cholangiogram—catheter overlying part of the common duct. Pancreatic duct well visualized.

tive cases of both calculous and noncalculous lesions selected from the present series in which the diagnosis and subsequent decisions were made during surgery on the basis of routine operative cholangiograms.

There are many cases in which the decision to do a choledochostomy is not difficult. A history of jaundice together with the presence of small stones in the gall bladder, a dilated cystic and a dilated common duct do not permit any other decision. Even in these clear cut cases, however, it has proved to be a definite advantage to know the number and location of the common duct calculi before opening the duct (Fig. 2 a, b, c, d).

There are many other cases in which the decision to do a choledochostomy is not clear cut. It is in these cases that operative cholangiography plays an important rôle. Many of them would not be explored, especially if obesity or a borderline cardiac status were an added factor. It is this group that probably

Many media have been used for visualization of the biliary duct system including lipiodol thorotrast hippuran 35 per cent and 70 per cent diodrast (3 12 17) In the present study 70 per cent diodrast has given the best results. Lipiodol is difficult to inject through a small needle and because of its failure to mix readily with bile it gives a higher percentage of false positives. Due to its greater density small stones may also be more readily obscured by it The diodrast should be warmed to body temperature before injection Previous instillation of a drop of it into the conjunctival sac is employed in an attempt to avoid the infrequent reactions from this material A quarter inch 22 gauge needle is inserted into the common bile duct A small caliber needle of this sort is preferred to minimize leakage of bile after it is withdrawn This needle is connected to a 30 cubic centimeter syringe by means of a foot or more of amber rubber tubing It is preferable to have the syringe and tubing filled with saline to avoid the introduction of air bubbles and to allow the location of the needle to be checked by the injection of a few cubic centimeters of saline inasmuch as it is often difficult to aspirate bile through this small needle After it is certain that the needle communicates with the lumen of the common duct, a syringe containing 70 per cent diodrast is substituted for the saline syringe. Twenty cubic centimeters of this opaque material are injected slowly to prevent sudden dilatation of the biliary tree This procedure generally requires 1 to 2 minutes.

Toward the end of the injection the surgeon announces its progress in cubic centimeters. This serves to warn both the anesthetist and x ray technician of the approaching roentgen exposure As the injection is completed the anesthetist takes control and signals to the technician to make the exposure during a period of respiratory arrest

Recently following Sosman's suggestion a fractionated method of injection has been tried (16 19) In the present series, this has consisted of three injections of 5 5 and 10 cubic centimeters with films being taken after each injection This should obviate the possibility of small stones in the common duct being obscured by the large quantity of con-

trast media in a distended duct. Experience with this technique small amounts of dye being used, has shown better visualization of the anatomy of the common duct, especially in the region of the sphincter of Oddi.

The anesthetic used in this series was intratracheal nitrous oxide, oxygen, and ether. This has the advantage of permitting the patient to be held in respiratory arrest for the 1 to 2 seconds required in making a roentgen exposure. Respiratory arrest is accomplished by having the anesthetist wash out sufficient carbon dioxide in the 5 minute period prior to the injection of the diodrast. Curare has not been used in this series as a means of stopping breathing Spinal anesthesia was not used because of relaxation of the sphincter of Oddi with resultant poorer visualization of the biliary system (5)

Roentgenograms are taken by means of any standard portable shockproof unit, operating at 90 kilovolts, 30 milliamperes, and an exposure of 1 to 2 seconds. For better detail a Lysholm grid is attached to the cassette. Motion is eliminated by synchronizing the exposure with the period of respiratory arrest The cassette is then removed from the tunnel for processing of the film During the time necessary for this the gall bladder is exposed, unless unavoidable indications for exploration of the common duct require this to be done first. Wet films are available for inspection and interpretation before the completion of either procedure. If common duct exploration is necessary a repeat cholangiogram is taken through the T tube before the abdomen is closed. The second set of wet films is usually ready for interpretation before the abdominal closure is completed Any further exploration may be accomplished at the comparatively simple cost of removing a few sutures.

RESULTS

Routine operative cholangiograms were done in 30 cases during the past year 1946-1947 An analysis of the results revealed that the procedure should be judged, not only as to the technical adequacy of each individual examination but also as to the amount of information which could be furnished the surgeon under optimal conditions.

Technical results were found to be directly dependent upon the team's experience with the procedure. The team consisted of a surgeon, radiologist, anesthetist, and technician. A number of different teams took part in the present study so that the results could not be expected to be as good as if one team had done the entire group.

Of the group of 30 cholangiograms, 17 cases (56%) were excellent, 10 cases (33%) were diagnostically adequate but had technical shortcomings, and 3 cases (10%) were failures. To account for the failures, in one instance the needle slipped out of the common duct and the diodrast was deposited as an indiscriminate mass in this region. In the second, due to uncertainty that the needle was in the common duct, it was withdrawn and reinserted. Diodrast leaked from the hole in the common duct at the site of the initial puncture and obscured the detail. The third case was a false positive in which two spherical negative densities were visualized near the junction of the cystic and common ducts. Subsequent common duct exploration and T-tube cholangiogram showed no calculus. The artefact was attributed to air bubbles. Increasing familiarity with the procedure and the difficulties involved has greatly raised the percentage of diagnostic films during the past few months. Of the last 15 cholangiograms, 12 (80%) were excellent, 2 (13.3%) were diagnostically adequate, and 1 (6.7%) was a failure (Fig. 1).¹

Although the objective of operative cholangiograms as first used was the determination of the presence of common duct calculi, they have proved a diagnostic aid in other lesions involving the hilar duct system, such as tumors of the head of the pancreas, common duct or liver inflammation or spasm of the sphincter of Oddi, indirectly pancreatitis or hepatitis. The true anatomical picture of the extrahepatic and intrahepatic systems is well visualized (1-17). Following are representative

¹Since this paper was presented for publication, an additional 30 patients have received routine operative cholangiography. There has been marked improvement in the technical excellence of the films due largely to the adoption of the routine of 3 serial cholangiograms with 5 cubic centimeters of the contrast media injected each time. Eighty per cent of the films were excellent, 10 per cent diagnostic, and 10 per cent failures. It is of interest that the failures occurred with few residents not entirely familiar with the procedure.

Fig. 1. Normal operative cholangiogram—catheter overlying part of the common duct. Pancreatic duct well visualized.

cases of both calculous and noncalculous lesions selected from the present series in which the diagnosis and subsequent decisions were made during surgery on the basis of routine operative cholangiograms.

There are many cases in which the decision to do a choledochostomy is not difficult. A history of jaundice together with the presence of small stones in the gall bladder, a dilated cystic and a dilated common duct do not permit any other decision. Even in these clear cut cases, however, it has proved to be a definite advantage to know the number and location of the common duct calculi before opening the duct (Fig. 2 a, b, c, d).

There are many other cases in which the decision to do a choledochostomy is not clear cut. It is in these cases that operative cholangiography plays an important rôle. Many of them would not be explored, especially if obesity or a borderline cardiac status were an added factor. It is this group that probably

Fig. 1. a, A 26 year old white male with a 3 year history of severe upper abdominal colicky pain requiring morphine for relief and associated with yellow sclerae on one occasion. X-ray showed a functioning gall bladder with multiple calculi. visualized. c, A 29 year old white male with 3 year history of postprandial epigastric distress activated by greasy food. X-ray history of jaundice. The gall bladder failed to visualize by X-ray on repeated examination. Operative cholangiogram showing 3 negative opacities in the common duct. Notice reflux into pancreatic duct. d, Operative cholangiogram through T-tube after removal of 3 calculi from duct. Duct clear. Spasm of sphincter of Oddi.

contributes the largest proportion of the 10 per cent of common duct stones which Lahey estimated were overlooked at operation. Routine use of operative cholangiography should greatly reduce this figure. It should also prevent the surgeon from exploring a certain number of ducts which appear dilated but contain no calculi. The ability to avoid a common duct exploration in the bad risk patient with confidence that the duct is not involved is certainly worth while.

CASE 1. A 51 year old white male was admitted to the hospital with a complaint of indigestion and intolerance to fatty foods which produced nausea and epigastric distress. Past history revealed two attacks of transient jaundice associated with indigestion, nausea, vomiting and pain in the epigastrium. The pain had not been severe enough to require morphine. The patient had been hospitalized

3 years prior to admission for coronary thrombosis.

Physical examination was essentially normal. Roentgen examination revealed a poorly visualized gall bladder containing calculi. Icteric index was normal. Electrocardiograph was consistent with an old coronary thrombosis.

Surgery revealed a thickened gall bladder containing large and small calculi, the largest 3 by 2 centimeters. The cystic duct was small, common duct of average size. Operative cholangiogram showed a common duct which was not distended and contained no calculi. The gall bladder was removed. Subsequent follow-up 3 months later revealed no indigestion or complaints referable to the gastrointestinal tract.

A patient with evidence of coronary sclerosis is obviously not a good risk for unnecessary exploration of the common duct.

Of equal importance in order to prevent overlooking calculi at the time of exploration,

Fig 3 a, A 35 year old white female with an 18 month history of indigestion and epigastric pain without jaundice. A poorly functioning gall bladder was visualized by x-ray. b Operative cholangiogram showing several negative densities in the common duct. c Operative cholangiogram through T tube after removal of 3 calculi from common duct and passage of a No. 12 French woven catheter into duodenum. Negative density still present in region of ampulla. d, Operative cholangiogram through T tube after removal of a fourth calculus from common duct. Duct clear. Some spasm of sphincter.

is the repeat cholangiogram taken through the T tube before the abdomen is closed. In 1 case in which exploration, irrigation and passage of a No. 12 French woven catheter into the duodenum disclosed no further calculi, repeat cholangiogram showed a stone still present in the ampulla. The partially closed abdomen was reopened and the stone removed with some difficulty by means of a scoop. The final film showed spasm of the sphincter of Oddi due to operative manipulation but no additional calculi (Fig 3 a, b, c).

Exploration of the common duct at the time of the removal of an acutely inflamed gall bladder is a difficult and hazardous procedure. The edematous indurated fat surrounding the duct bleeds easily and increases the danger of inadvertent trauma. A history of moderate jaundice which has subsided or the residual presence of slight jaundice make accurate in-

formation about the common duct essential. This may be obtained after the gall bladder has been dissected from fundus to duct. A small needle is inserted into the cystic or common duct and a cholangiogram is taken. Due to some difficulty in being certain of the position of the needle in the lumen of the cystic duct, a small cannula has been used recently with good results. A roentgenogram showing a common duct without calculi or dilatation and with dye in the duodenum adds greatly to the surgeon's peace of mind and avoids a difficult and extensive procedure.

CASE 2. A 27 year old white male was admitted to the hospital with a 9 year history of recurrent attacks of right upper quadrant pain associated with vomiting. He had been jaundiced on two occasions for several days. Two days prior to admission to the hospital he again commenced to have severe right upper quadrant pain, nausea and vomiting similar to his previous attacks.

Fig. 4. Case 2. Cholangiogram taken during operation for acute cholecystitis in patient with past history of jaundice. Common duct without calculus, cystic duct stump and pancreatic duct are isolated.

Past history revealed typhoid at the age of 13. The patient appeared moderately acutely ill. There was increased resistance in the right upper quadrant of the abdomen with marked tenderness and rebound tenderness referred to this area.

Laboratory examination revealed white blood cells, 10,100. 80 per cent polymorphonuclear leukocytes. Urine normal.

Scout film of the abdomen was negative.

At operation an acutely inflamed adherent gall bladder containing two large calculi was removed from fundus to duct. Operative cholangiogram showed a normal common duct without calculus (Fig. 4). Convalescence was uneventful.

Occasionally in spite of adequate exposure the anatomy of the common and hepatic ducts is not clear especially at secondary operations. When this is true it is most helpful to be able to clarify the anatomy by means of a cholangiogram with the dye injected into the first duct containing bile that is encountered. The resulting picture may eliminate much fruitless searching and prevent injury to the duct system as well as visualizing the pathology present.

Fig. 5. Case 3. a, Operative cholangiogram through catheter showing short segment of common duct with constrict angulation and narrowing but without calculi. b, Operative cholangiogram showing proximal portion of duct system and intrahepatic branching of hepatic ducts.

CASE 3. The patient was a 37 year old white male with a 12 year history of recurring episodes of painless jaundice lasting about a week at a time and coming on several times a year. With his entry into the Army in 1932 the attacks became monthly and were associated with diarrhea. A more severe attack of jaundice occurred in 1944, 2 years prior to admission, was diagnosed infectious hepatitis and he was returned to this country. Following a severe attack of abdominal pain radiating to the back, cholecystectomy was performed 6 months later in an Army hospital. The gall bladder was said to have contained stones. Mild intermittent jaundice continued and he received a disability discharge. For the last 6 months prior to admission, the patient had been jaundiced constantly and had had discomfort in his operative scar.

Family history revealed a brother who had had several months of common duct drainage following explantation of the duct for calculi.

Admission physical examination showed mild icterus and slight abdominal tenderness below the xiphoid.

Laboratory examination revealed an icteric index of 25, normal liver function, normal fragility test, and negative duodenal drainage.

Fig. 6. a, A 43 year old colored male with a 3 week history of fatigue and aching abdominal pain and a 3 day history of jaundice. The gall bladder failed to visualize by x ray and the laboratory findings suggested obstructive jaundice. Operative cholangiogram showing dilated biliary duct system with a complete block in the region of the ampulla. b, Opened operative specimen showing carcinoma of ampulla blocking the common duct. c, A 55 year old white male with a 3 month history of itching of the skin and a 6 week history of epigastric pain and jaundice. X ray examination of the gastrointestinal tract showed extrinsic pressure on the duodenal cap. Laboratory studies suggested obstructive jaundice. Operative cholangiogram through a cannula in the cystic duct showing the cystic and hepatic ducts narrowed and the duct system dilated proximal to a complete obstruction. This was found to be due to carcinoma of the common duct involving both hepatic ducts and the cystic duct.

Operation was performed for probable common duct stone. The distance between the portal fissure and the duodenum was not over 3 centimeters. The common duct appeared to be 2 centimeters in diameter but had a lumen which was difficult to find and which admitted a No. 10 French catheter snugly. Operative cholangiogram through this catheter identified the lower end of the common duct with no calculi present and dye in the duodenum (Fig. 5a). A constant narrowing and angulation of the duct in the region of the sphincter was diagnosed as probable inflammation of the sphincter of Oddi with spasm. A catheter inserted in the opposite direction visualized the intrahepatic portion of the duct system (Fig. 5b). T tube drainage was instituted. The patient continued to have an icteric index up to 33 and had episodes of mild jaundice. He remained afebrile and asymptomatic with the T tube still in place after 5 months. Forty centimeters of water pressure through the T tube produced discomfort

and 50 centimeters caused definite pain. Nitroglycerine and atropine had no effect on the duct pressure. The T tube had been clamped for the month prior to his last follow up without a return of jaundice or pain.

Operative cholangiography was of great value in this case in proving that the small duct obscured by a greatly thickened wall was really the common duct. Without its identification the proximal portion of the biliary tract would have been more difficult.

Operative cholangiography has also proved useful in the diagnosis of tumors of the bile ducts and head of the pancreas. Dye injected into the dilated portion of the duct system shows the nature and completeness of the block without dissection in the region of the

Fig. 7 a, Right hepatic duct displaced to the left by tumor in right lobe of liver. Left hepatic duct is not involved. b, Normal, right and left hepatic ducts and tributaries. Reprinted through courtesy of Dr. Paul Rudström (*Acta Radiologica*).

tumor. Where doubt still remains at surgery as to whether or not a tumor exists in the ampulla or head of the pancreas surrounding it it is much simpler to take a cholangiogram than to open the duodenum and explore the region (Fig. 6 a & b c).

CASE 4. A 26 year old white male was admitted to the hospital with a two year history of dull aching epigastric pain. The pain occurred after eating, was sometimes colicky and did not radiate. Six months prior to admission he had noticed anorexia and had lost a total of 50 pounds up to the time of admission. Six weeks before admission he became icteric. This cleared somewhat on bed rest and a fat free diet and then recurred. Past history was noncontributory except for a period of moderately severe alcoholism following discharge from the Navy.

Physical examination showed a well developed deeply icteric white male who had obviously lost considerable weight. There was direct and rebound tenderness in the upper abdomen. The liver and spleen were not felt.

The icteric index varied from 110 to 190 cephalin flocculation test 4+ 40 per cent retention of bromsulphalein in 30 minutes normal fragility test. Serum amylase rose to 96. X-ray examination of the upper intestinal tract revealed a normal esophagus, stomach and duodenum. Cholecystograms were not taken because of the icterus. The patient's upper abdominal tenderness increased and localized in the right upper quadrant and his temperature commenced to swing up to 100 degrees daily.

Exploration was performed with a diagnosis of acute and chronic cholecystitis with common duct stone. At operation the gall bladder was quite dis-

tended, would not empty but contained no calculi. No calculus was felt in the common duct. The head of the pancreas was quite firm, and a diagnosis of carcinoma was considered. A cholangiogram was taken with a needle in the lumen of the common duct. This showed a common duct of normal appearance with dye entering the duodenum readily. Biopsy specimens were taken from the pancreas and liver which were later reported as normal pancreas and acute inflammation of the portal areas of the liver. The patient had an uneventful convalescence and regained his appetite. The icteric index dropped to 55 and the bromsulphalein test returned to normal. He was discharged on the 19th postoperative day feeling well.

DISCUSSION

The success of routine operative cholangiography is directly dependent upon the ability to produce a cholangiogram of good diagnostic quality with a negligible loss of time. The closest co-operation of the surgeon, radiologist, anesthetist and x-ray technician is essential. Passive indifference on the part of the surgeon or radiologist toward the perfection of operative cholangiography only negates the procedure. Even the slightest respiratory motion during the course of exposure due to lack of co-ordination by either the anesthetist or the technician can entirely destroy the value of the examination.

Due to the various components involved, although operative cholangiography is not

difficult, it seemed wiser to follow Mirizzi's example and attain maximum proficiency by making the procedure routine. This had the added value of thoroughness in an effort to prevent overlooking biliary tract disease. Russell Best is of the opinion that cholangiograms are as essential to the surgeon doing gall bladder surgery as a gastrointestinal series is before considering a gastric resection (2).

Interpretation of cholangiograms is not difficult provided one bears in mind the various artefacts that may occur and how to avoid them. Common causes for misinterpretation are the presence of air bubbles in the common or hepatic ducts, the inadvertent placement of the tubing carrying the opaque material too far medially so that it overlies and obscures the extrahepatic biliary system, and failure to insure proper placement of the needle in the lumen of the common duct which causes dye to pool in the vicinity. The injection of dye must not be too rapid or the biliary tree will overdistend again giving false evidence of pathology. All of these mishaps can usually be remedied by repeating the cholangiogram as soon as the wet films are inspected. The needle hole in the common duct has generally ceased leaking and can be disregarded. The additional time loss is not great.

Most common duct calculi are non-opaque. If precautions have been taken to exclude air from the system, negative shadows in the intrahepatic or extrahepatic systems are indicative of calculi. Although it is possible that negative shadows might be due to blood clot or intraductal tumor, these have not been present in our experience. However, false negative shadows caused by borders of vertebrae and gas in the intestine may be encountered. Deviation or deflections of either hepatic duct or the main branches may be due to space occupying lesions. Rudström described 2 cases of intrahepatic disease which were diagnosed by means of operative cholangiography. In one instance a tumor of the right lobe of the liver was demonstrated displacing the right hepatic duct (Fig. 7 a and b). Marked distention of the hepatic radicles is

indicative of a mechanical block. Tumors of the ampulla of Vater or head of the pancreas are funnel shaped or irregular. Spasm of the sphincter of Oddi may be encountered if dye is injected too rapidly.

In the past the objections to operative cholangiography have been poor films, insufficient information obtained and too much time consumed in the examination. Attention to the aforementioned details, perfection of technique and consequent improvement of interpretive diagnosis should largely dispose of these objections.

SUMMARY

1. The results of a year's experience with the routine use of operative cholangiography have been presented.

2. A simplified technique using readily available equipment is described.

3. The types of cases in which operative cholangiography has proved useful are discussed.

4. Reasons for technical failures and false positive diagnoses are mentioned with suggestions for their correction.

ATRAUMATIC LOW THIGH AMPUTATION

Further Modification of and Experiences with Technique

FELIX PEARL, M.D. F.A.C.S. San Francisco, California

SINCE 1936 the writer has been especially impressed with low thigh amputation performed according to the basic principles advanced by Callander (3,4) in 1935 in which no muscle bellies are cut. The operation was originally devised to lessen shock and to prevent the proximal spread of infection. Attention was directed to the following anatomical facts: (1) The popliteal space is a closed space; the intact upper limit of which acts as an effective barrier to the spread of infection. (2) Section only of tendon preserves this bulwark against infection, whereas section of the fleshy portions of muscles destroys it. (3) The tissues of the lower thigh, knee and upper leg are supplied by the deep femoral artery which is rarely affected by occlusive arterial disease even in patients in whom the superficial femoral artery is completely occluded.

In the Callander technique long viable skin flaps are fashioned from the upper leg; all transections of muscles are done through their tendinous insertions; the bone is sectioned through the flares of the condyles; the patella is excised and its bed made available as a cover for the bone end; the skin and subcutaneous tissues are approximated loosely. As the hamstrings draw the posterior flap cephalad, the patella bed is directed over the bone, and the skin flaps retract to fit snugly about the bone. The technical and anatomical points in this procedure lend themselves very favorably to amputation for peripheral vascular disease and the author continued to use this technique in the first fifteen amputations for peripheral vascular disease done according to the Callander principle. Because of a somewhat high percentage of delayed healing, persistent edema of the stump and mobility of the patella bed which interfered with the function of the prosthesis, the writer modified the procedure and in 1941

he reported details of his new technique (1), which in general consisted of the following changes: (1) The skin flaps were of the "fish mouth" type and of similar length and contour. (2) The patella and the peripatellar tissues were completely removed. (3) The bone was not sectioned through the condyle flares but through the medullary portion of the femur 2 1/2 to 3 centimeters above the epicondyles.

The author's modification produced a definite improvement in the tendency to heal per primam to the contour of the stump and in the fitting and functioning of the prosthesis. It was usual, however, for an appreciable amount of clear or slightly bloody fluid to form in the stump and be discharged for 3 to 5 days through the openings left at the apex of the suture line. Often there was enough fluid to soak the dressings. In some cases the formation of fluid continued after the suture line healed, requiring its evacuation. In a good number of cases evidence of fluid accumulation in the stump persisted for many weeks, even months, causing edema in the region of the suprapatellar bursa which delayed the shrinking process and interfered with the satisfactory use of the prosthesis.

In the author's modification, as well as in the original technique, the suprapatellar bursa remains intact, and a considerable portion of the synovial membrane of the bursa is left in the stump. This membrane may well continue to secrete synovia and be responsible for the discharge of fluid which often occurs. In an attempt to eradicate this factor, the author has further modified the procedure, removing the synovial membrane in accordance with the technique described and illustrated below.

TECHNIQUE

The operation proceeds as usual with the formation of skin flaps; tenotomy of the medial hamstrings; opening of the popliteal space; section of the vessels and nerve; tenotomy of

From the Department of Sympathetic and Vascular Surgery, Mt. Zion Hospital.

the biceps femoris and tensor fascia femoris scalping back the anterior flap, mobilization of the posterior flap entering the knee joint through the tendon of the quadriceps femoris and section of the retinacula genu. These steps are described in detail and illustrated in a previous article by the author (17). The anterior flap is drawn sharply cephalad exposing by inversion the depths of the suprapatellar bursa, and the additional step is carried out as follows (Fig. 1).

The edges of the synovial membrane are grasped with forceps and the membrane gently separated from the underlying structures. The dissection is begun medially first freeing the membrane from the underlying muscle fibers of the vastus medialis then laterally from the tendinous fibers of the vastus lateralis as the dissection is carried toward the midline. The membrane is loosely attached to these structures by the interposition of a well defined layer of areolar tissue of definite thickness and separates easily. When the undersurface of the quadriceps tendon is reached however the membrane becomes thin and intimately attached to the tendon so that a clean cut separation is made impossible. The membrane is freed as much as possible and the undersurface of the quadriceps tendon is scraped clean of the remainder with a curette. If desired a thin shaving of the tendon may be removed with the synovial membrane in order to eliminate the membrane completely but the tendon is extremely tough and a clean removal of a slice is difficult. As the membrane previously freed on each side now medially is mobilized it is gradually reflected caudad off the vasti the retinacula the tendon of the quadriceps femoris and the anterior surface of the femur to a point caudad to the proposed site of bone section (Fig. 1). The separation from the femur is also easily accomplished because of the interposition of loose areolar tissue. Thus the entire secreting membrane forming the suprapatellar bursa is removed with the specimen. The section of the bone and the closure are carried out as previously described (17).

In 1943 Pearl and Misrak (19) reported their experience with the atraumatic amputation through the lower thigh a technique which

Fig. 1. The suprapatellar bursa has been entered through the tendon of the quadriceps femoris and the retinacula sectioned. The anterior flap has been drawn sharply cephalad, and the depths of the suprapatellar bursa have been exposed by inversion. Hemostats grasp the edges of the synovial membrane which forms the bursa. The synovial membrane has been freed from the vasti laterally and partially from the undersurface of the quadriceps tendon medially. It will be dissected caudad to a point distal to the proposed bone section indicated by the broken line, and will be removed with the specimen.

cuts no muscle bellies. Several additional points which are the result of further experience with this method of procedure are worthy of mention.

Skin flaps. In fashioning the posterior skin flaps the knee should be held in about 15 degrees flexion. If the flap is marked out with the knee in full extension it will be too short. In legs with a goodly amount of subcutaneous fat the flaps should be about equal in length in thin muscular legs the posterior flap should be made about 1 to 1½ centimeters longer because of a greater tendency to retract. In making the curve for the posterior flap the stump contour will be improved if care is taken to eliminate the dog ears by avoiding a sweep which is too circular.

Treatment of sciatic nerve. The sciatic nerve was formerly injected with absolute alcohol to prevent neuroma formation. There is no apparent difference in postoperative pain or phantom limb sensation when the alcohol is omitted. The nerve is gently drawn down all ways ligated firmly as high as possible with fairly strong material in order to control the bleeding from the cut end and sectioned about 2 centimeters distal to the ligature with knife

or razor blade—never with scissors. The ligature is left long so that the end may be inspected just before closure is made as bleeding from the arteria comitans is a common cause of hematoma and delayed healing. It is not unusual for the nerve to require a second ligature.

Saving the bone The Gigli wire saw is in the author's hands, the most efficient and a traumatic instrument with which to section the bone. Some difficulty may be encountered in holding to the perpendicular in both planes and he has often asked an observer to check the alignment as the section progressed. The assistant should support the bone in its original alignment until the bone has been completely divided in order to prevent fracture during the last portion of the section. The periosteum is allowed to reach the bone end no cuff is removed. Bleeding from the bone is another frequent cause of hematoma in the stump and should be thoroughly controlled before closure. More recently a thin piece of absorbable oxidized cellulose cut to fit and applied to the bone end has been used for hemostasis. The author prefers it to bone wax.

Special care of biceps tendon If the bone section is high or the biceps long the latter may tend to prolapse from the wound through the spaces left for drainage (see closure). To avoid this the cut end of the biceps is anchored to the tissue about the bone with a suture.

Irrigation of the wound The use of saline irrigations removes bone dust, clots, and loose fat and tends to promote per primam healing. It also demonstrates oozing points which may require attention.

Control of bleeding This is very important before closure. Every bleeding point should be meticulously controlled with ligature or coagulation. The time spent in this step may be long and the task tedious, but the operator will be rewarded by an increased percentage of clean trouble free wounds which heal per primam. An extra half hour grudgingly devoted to this chore, when required is a small price indeed when compared to the weeks and often months of painful time-consuming dressings which healing by secondary intention often entails.

Closure In our early cases, closure was effected with interrupted silk which passed through skin and subcutaneous tissues, every other stitch being left untied to allow for drainage loose sutures being drawn tight on the third or fourth day. It was soon found, however that drainage passed through the openings left at the apex only and that it was unnecessary to leave openings for drainage in the lateral arms of the incision. Before any sutures are placed, the fit of the flaps is checked with towel clips and excess skin, if present, is excised. It is rarely necessary to alter the skin flaps if they are carefully planned. Beginning at the most proximal portions of the lateral arms, the approximation sutures of No. 1 Deknated silk are then passed through skin and subcutaneous tissues until the region of the apex is reached. In this area, the sutures are placed as usual, but every other stitch is left loose and knotted at the ends for a distance of about 3 centimeters on each side of the midline. This procedure allows any retained blood or fluid to escape during the first few days. As soon as the drainage stops, the remaining sutures are tied. Drainage material is never used.

Dressing A well executed operation may be spoiled by an unsatisfactory dressing. Additional pressure pads are placed so as to obliterate the "hamstring pouch" posteriorly. The remainder of the stump is enclosed in cotton abdominal pads held in place with a snugly fitting gauze bandage. Over this bias-cut stockinette is applied so as to give firm and even pressure to the entire stump. The pressure should be firm enough to eliminate dead space and control capillary bleeding but not enough to interfere with the circulation of the tissues. The actual application of the proper pressure is a matter of experience. In applying the bandages rotation of the soft tissues of the stump should be guarded against. Splints interfere with the retraction of the posterior flap and with the movement of the stump and are therefore not used.

Postoperative care As soon as the anesthesia has worn off the patient is encouraged to move the stump. The stump rests horizontally on the bed and is not raised on a pillow for fear of causing flexion contractures. He is

encouraged to walk with crutches as soon as possible usually on the first or second day. The stitches in the lateral arms of the wound may be removed on the fifth day but those at the apex should be left until the twelfth or fourteenth day. The hamstring pull is sometimes strong enough to cause strain on the suture line at the apex and the additional support afforded by the sutures is advisable until the union of the skin and subcutaneous tissues is sufficiently firm.

Anesthesia In almost all of our patients low thigh amputation has been done under low subarachnoid block. This anesthetic causes little or no disturbance of the blood pressure since only the vasomotors of the lower extremities and the saddle area are affected. The simultaneous paralysis of the vasoconstrictors to the legs allows the fullest possible vasodilatation. Premedication with morphine scopolamine and nembutal acts to minimize psychic trauma. The majority of the patients sleep through the procedure. The only possible trauma is psychic due to the noise of the saw since the subarachnoid block isolates the site of operation from any sensory connection with the cerebrum most of the patients have no memory of the operation itself. The risk of low subarachnoid block is so slight and the results so gratifying that it leaves little to be desired.

The author is fully aware of the use of refrigeration as a method of limb anesthesia. The concept was advanced early in the development of refrigeration that tissues thus cooled were merely in a state of suspended animation or hibernation that all physiological processes came to a standstill and that the tissues when allowed to return to normal temperatures resumed their functions uninjured and unchanged. The experimental work of Large and Heinbecker (789) Bruneau and Heinbecker Brooks and Duncan however showed without question that refrigeration causes definite injury to tissues. In most instances of refrigeration anesthesia a tourniquet is necessary above the site of amputation. The operation is therefore done through tissues which have been subjected to circulatory arrest plus refrigeration—two conditions which diminish the local resistance to infection and

retard the healing process. That these complications may occur is attested to by clinical reports of slough of tissues distal to the tourniquet.

When there is a necessity for delay in amputation either because of some general condition of the patient which makes waiting advisable or because of spreading infection and toxemia from the affected member refrigeration is without question a valuable procedure. The author fully agrees with the tenets advanced by writers already quoted which include the following conditions for the use of refrigeration: (1) there must be a necessity for delay in amputation; (2) the tissues to be refrigerated are hopelessly diseased and their removal is mandatory—viable or potentially viable tissues are not refrigerated; (3) the tourniquet is placed immediately proximal to the lesion and is not thereafter disturbed; (4) when amputation is performed the tourniquet is left in place but the operation is done under subarachnoid block or some other form of anesthesia through nonrefrigerated tissues.

The technique of atraumatic low thigh amputation as now performed by the author has been developed over a period of 11 years and has proved itself a highly desirable operation. It is applicable to diseases of the peripheral arteries as well as to any other condition requiring low thigh amputation in which the tissues about the low thigh knee and upper leg are not traumatized nor inflamed. It causes little or no shock has an extremely low mortality and results in a stump which meets the approval alike of patient, surgeon and limb maker. The stump is mobile painless and bearing and its conical shape lends itself well to the prosthesis. The shrinking process proceeds rapidly. Phantom limb sensations are present in every patient but in none have they been a source of unusual annoyance. None of the amputees have had painful stump syndrome or symptoms suggesting neuroma formation.

AN EXPERIMENTAL APPROACH TO THE PROBLEM OF INCREASING THE BLOOD SUPPLY TO THE LUNGS

Preliminary Observations on the Use of Plastics

ELLIOTT S. HURWITT M.D., F.A.C.S., New York, New York

A CONSIDERABLE impetus to the study of congenital cardiac defects has resulted from the work of Blalock and his associates. This group has shown that relief of cyanosis and improvement in exercise tolerance may be obtained in a substantial proportion of patients exhibiting the tetralogy of Fallot by the construction of a vascular shunt from a large systemic artery to one of the pulmonary arteries. The modification proposed by Potts consisting of an anastomosis between the aorta and a pulmonary artery is an additional development of the same principle.

An investigation was undertaken in this laboratory of the possibility of employing a more central approach to the problem of increasing the blood supply to the lungs. Attention was focused on the right side of the heart in an effort to devise a method which would avoid the creation of an artificial arteriovenous communication. Two avenues of approach were explored: (1) circumvention of the pulmonary valve by a shunt from the right ventricle to the proximal portion of the main pulmonary artery and (2) dilatation of the pulmonary valve ring.

EXPERIMENTAL DATA

1. Intubation of the right ventricle and the pulmonary artery by-passing pulmonary valve. Polyethylene tubing was selected as the most promising of the available materials. As demonstrated by Ingraham, Alexander and Matson, polyethylene is a plastic substance characterized by lightness, malleability, flexibility, ease of adjustment and ease of sterilization. It is chemically inert and nonirritant.

From the Department of Pathology of the Harvard Medical School and of the Children's Hospital and the Infant Hospital. Aided by grant from the Sarah W. F. Fellowship Fund.

ing to living tissues. When the flow of a sufficient volume of blood is maintained, clotting may be avoided for a considerable period of time. Practical application of this property has been made by Myers in intravenous therapy and by Diamond and Thomas for replacement transfusions in the treatment of severe erythroblastosis fetalis. Hackworth reported replacement of the thoracic aorta in dogs.

The operations were performed on cats weighing about 10 pounds and anesthetized by sodium pentobarbital administered intraperitoneally. Controlled rhythmic inflation of the lungs was maintained by air delivered under positive pressure through an intratracheal tube. The left pleural cavity was entered through a left parasternal incision with division of the 3rd, 4th and 5th costal cartilages. The pericardium was incised anterior to the phrenic nerve and the pericardial flaps held apart by traction sutures (Fig. 1 a). Two vertical parallel hemostatic sutures of fine silk were placed in the anterior wall of the right ventricle and 2 similar sutures in the anterior wall of the pulmonary artery a short distance above the valve ring (Fig. 1 b). In the later experiments a pursestring suture was also placed between the hemostatic sutures in the pulmonary artery. Two anchoring sutures previously placed in the wall of the longer arm of the prebent polyethylene tube were passed horizontally between the hemostatic sutures in the pulmonary artery. An oblique incision was made in the square marked out by the 4 sutures; the end of the tube inserted into the lumen of the pulmonary artery and the hemostatic sutures tied to each other. The pursestring suture was secured and each anchoring suture tied (Fig. 1 c). The ventricular end of the tube was inserted by a similar technique (Fig. 1 d). The location of the ends of the tube viewed from within the heart may be

seen in Figure 1 e drawn from the postmortem findings in cat 20. The pericardium was not sutured, and the wound was closed in layers air being removed from the pleural cavity by suction through a catheter during the closure.

The results obtained in this series of operations were as follows. Of the 11 animals explored the intubation was completed in 3. Three cats died during attempted implantation of the tube due to hemorrhage or other technical difficulties. Operation in 5 instances was terminated by suture of the incision in the pulmonary artery following failure properly to insert the tube. At postmortem examination performed subsequently in the course

of other experiments there was no evidence of narrowing of the lumen of the pulmonary artery or of thrombus formation at site of suture.

The 3 cats in whom circumvention of the pulmonary valve was completed provided material for subsequent observations. One animal died 12 hours postoperatively and the other 2 were sacrificed on the 36th and 47th postoperative days respectively. In no instance was there noted any displacement of the ends of the tubes from their location at the time of operation. In every case the lumen of the tube was occupied by a partially organized adherent thrombus, so that it was not possible to estimate how long the flow of blood through the tube observed at operation, had been maintained. The reaction around the outer walls of the tubes consisted for the most part of a thin fibrous membrane.

2. *Dilatation of the pulmonary valve.* The need for a light, nonirritating prosthesis which could be inserted into the pulmonary valve ring and left *in situ* was met by the use of lucite. Intubation of the aorta of dogs with lucite tubes was reported by Hufnagel, who found no thrombosis after several months of observation. In our experience freedom from clot has been dependent on a highly polished, absolutely smooth inner surface.

The final shape of the lucite tubes employed for dilatation of the pulmonary valve is seen in Figure 3. The tube is slightly tapered, and the leading edge bears 2 shallow circular grooves on its outer surface for greater purchase. A flange 1 millimeter in width around the following end of the tube was designed to impede expulsion of the tube through the valve ring. The technical problem of controlling the position of the tube during its insertion through an incision in the anterior wall of the right ventricle was overcome by modifying an ordinary dura clip forceps so that the ends were splayed slightly outward. A lucite tube fitted over the tips of such an instrument may be held snugly without slipping off or sliding back on handles of forceps.

The surgical approach to the right ventricle was the same as that employed in the previous experiments and the same exposure was obtained. Two parallel rows of hemostatic sutures were placed in the anterior wall of the

right ventricle each row consisted of 3 sutures (Fig 2 a). An incision was made through the wall of the right ventricle between the rows of sutures and the end of the inserter armed with the lucite prosthesis was introduced to the region of the pulmonary valve. The inserter was disengaged and withdrawn hemostasis was effected by tying the parallel sutures (Fig 2 b). The location of the prosthesis was confirmed by palpation and the pericardial flaps were loosely approximated leaving room for drainage into the right pleural cavity. Closure of the chest wall was performed in the manner already described.

This procedure was attempted in 8 animals with 3 deaths either during operation or within a few hours thereof these fatalities were ascribed to acute blood loss. In the remaining 5 cats the tube was successfully inserted within the pulmonary valve ring. The survival times ranged from 8 hours to 5 months. In 2 instances there had been no postoperative displacement of the tube the second cat died on the ninth postoperative day. In 1 animal the tube was found in the lumen of the right ventricle and had obviously been too large a tube for the particular cat. Autopsy on the 2 remaining animals showed migration of the tube to the bifurcation of the pulmonary artery in one instance, and to the hilus of the right lung in the second case. The lumen of each of the tubes contained a small thrombus not completely occluding the prosthesis. There was no thrombus formation on the endothelium in contact with the tubes moderate infiltration of the vessel walls with lymphocytes was seen.

DISCUSSION

Jeger has described early unsuccessful attempts at the construction of vascular shunts by passing cardiac valves. The survival of animals in the present study following the insertion of a polyethylene tube circumventing the pulmonary valve provides a basis for an experimental program extending these observations. The occurrence of clotting within the prostheses was not unexpected as there was no obligatory flow of blood through the tubes. Since the degree of clotting is a function both of the size of the lumen of the tube and of the volume of blood flow both of these factors

Fig 2. Insertion of a lucite tube for dilatation of the pulmonary valve. a, Same exposure as in Figure 1. Two parallel rows of hemostatic sutures have been placed in the anterior wall of the right ventricle. The inserter is armed with the lucite tube. The dotted line indicates the proposed site of the myocardial incision through which the tube will be inserted. b, Showing the lucite tube inserted at the site of the pulmonary valve. The incision in the myocardium has been closed by tying the hemostatic sutures.

could be evaluated further by the use of larger tubes in dogs and by ligating the pulmonary artery within the by passed area. By these maneuvers in addition to survival and non displacement of the tube a shunt might be established that would remain patent and provide a tool for the study of vascular physiology and pathology. A similar technique could be applied to other chambers of the heart.

Survival following dilatation of stenosed valves in humans has been described by Tuffier and by Souttar. In these patients the aortic and mitral valves respectively were dilated by invagination of the vessel wall through the valve lumen over the finger of the operator. In the present investigation an attempt was made to insert a prosthesis that would maintain the valve in a dilated state. It has proved more difficult to keep such a tube from being dislocated than was the case with the by pass procedure. However with further refinements in technique a greater

degree of success has been obtained. Work is now in progress on the construction of a lucite prosthesis containing a valve to eliminate free pulmonary insufficiency. The application of the venous catheterization technique to animals in which such prostheses have been inserted might prove of value in the study of altered cardiac physiology and dynamics.

In the course of this study it was considered that a prosthesis either circumventing or dilating a cardiac valve should have a diameter conforming to that of the normal valve. In order to determine the average dimensions of the pulmonary valve in children the pertinent data from an extensive series of autopsy protocols were subjected to statistical analysis. It was found that the average diameter of the pulmonary valve varies only 1 millimeter between the ages of 2 and 7 years. The optimum diameter for a prosthesis intended to bypass or dilate the pulmonary valve in children of this age group should be about 14 millimeters.

The assumption has been generally accepted that the lesion responsible for the decreased flow of blood to the lungs in patients with the tetralogy of Fallot would not be amenable to local dilatation. It is well known that many of these individuals succumb within a few months of birth of a combination of cardiac lesions that is incompatible with survival. An impression was tentatively entertained that with the elimination of the patients presenting the most serious defects the surviving children might present a situation more favorable for direct surgical dilatation. An analysis of the autopsy material in this laboratory establishes the fact that such is not the case. There is no single stenotic or atretic lesion responsible for the hypoxemia associated with the tetralogy of Fallot but rather a combination of defects. Among the unpredictable variables in a given case are the degree of prominence of the crista supraventricularis, the status of the valve ring, the condition of the valve cusps, the size and location of the septal defect, rigidity of the base of the pulmonary artery, and extent and degree of atresia of the pulmonary artery.

While this would seem effectively to preclude any attempt at local dilatation of the pulmonary valve the circumvention type of procedure still merits consideration. The use of

a substance such as polyethylene tubing permits alteration in the ultimate shape of the prosthesis to conform to a given situation. It is not implied at this time that a technique such as this has been developed sufficiently to justify application in human material. Among other theoretical objections is the feature of a foreign body with a lumen of fixed size in a growing organ. Also as emphasized by Elliot Cutler any abrupt change in cardiac dynamics such as would be caused by this type of procedure might entail serious side effects. It is however suggested that this approach merits further development in the study of the dynamics and therapy of cardiac lesions.

SUMMARY

1. A technique has been described for the insertion of prostheses circumventing and dilating the pulmonary valve.

2. The properties of polyethylene and lucite have been described.

3. It is suggested that this approach may be useful in reproducing the effects of valvular insufficiency and in the study of the altered physiology and dynamics of cardiac lesions. A tentative program is proposed.

4. The possible application of this method to provide an increased blood supply to the lungs in the face of pulmonary stenosis is discussed.

CELIAC SYNDROME

VII Therapy of Meconium Ileus Report of Eight Cases with a Review of the Literature

ROBERT B. HATT, M.D. and PAUL E. WILSON, S.D., M.D. New York, New York

THE association of meconium ileus with pancreatic cystic fibrosis was first described by Landsteiner in 1905.

Since then there have been 11 other cases reported (3-5, 8-11, 14-16, 18) in each of which meconium ileus has been noted at operation and fibrocystic disease of the pancreas described following autopsy. Thus the coexistence of these two conditions has been well established. Seven additional cases have been found in the pathological records of the Babies Hospital.

Two hypotheses have been suggested to explain the association of abnormal meconium and fibrocystic disease of the pancreas. The first advanced by Landsteiner regards the abnormal meconium as primary and the changes in the pancreas as the result of intestinal obstruction; the second considers the changes in the pancreas as primary and the abnormality of the meconium as the consequence of lack of normal digestion of the meconium by pancreatic secretions. The latter view, which is generally held at present, has been strongly supported by the studies of Larber (6, 7).

Larber investigated the altered physical state of meconium in infants with meconium ileus. The meconium was so sticky and mucilaginous in consistency that the fingers and instruments were not easily extricated from the meconium after contact. The bowel is not able to propel this abnormal material and so the meconium becomes responsible for the intestinal obstruction. In vitro experiments by Larber showed that when this abnormal material was placed in contact with saline solutions of pancreatin (1 to 10%) at 37.5 degrees C. it was quickly reduced to a semiliquid or

liquid state. This observation provides the chief evidence for the view that the lack of pancreatic enzymes is the main factor responsible for meconium ileus.

It is obvious from a review of the literature as well as from our own experience that there are all variations and degrees of obstruction due to abnormal meconium in patients with cystic fibrosis of the pancreas. Many such patients have no obstruction at all. Some have transient meconium plugs which are passed following mild obstructive symptoms. Occasionally such a case responds to the instillation of pancreatin into the exposed gut at operation or to simple massaging of the meconium on into the large intestine. Larber has reported 4 cases in which the obstruction was relieved by the instillation of a 1 per cent pancreatin solution through an enterostomy opening. However, death occurred several days to a few weeks after the instillation from intercurrent infection.

We wish to emphasize that in this paper we are concerned with meconium ileus of the most severe form in which in our judgment it was inconceivable that the obstruction could be relieved by any of the above described conservative measures. The actual pathologic findings and surgical technique will be described in detail.

Hurwitz and Arnheim in 1942 reviewed the literature and were unable to find any instances of recovery. Swenson and Ladd, discussing this condition in November 1945, state:

This disease caused by pancreatic insufficiency is uniformly fatal. They reported that they were able to clear the intestinal tract using pancreatic solutions through an enterotomy, but that death resulted from pulmonary infections within a short time.

Table I summarizes all of the known reported and 15 unreported cases through Sep-

1. From the Babies Hospital, New York, and the Department of Pediatrics, Columbia University College of Physicians and Surgeons, New York.

gical service of the Babies Hospital on September 6 1945 because of failure to pass meconium since birth associated with the development of distention and vomiting of green material. The pregnancy had been uneventful and the family history was negative. The baby appeared well developed and well nourished with a markedly distended abdomen—39.5 centimeters in circumference. The rectum admitted the examining finger but was empty and small. A ray examination of the abdomen at this time revealed a moderate small gut distention confined for the most part to the left abdomen. The right abdomen was free except for one single distended loop seen in all films. A lipidol enema showed a small but essentially normal colon. The diagnosis entertained at the time was small gut obstruction due to atresia, stenosis or volvulus of the ileum. In consequence the abdomen was opened and a volvulus of a loop of ileum was found which on further examination appeared to be secondary to a meconium ileus. The volvulus was reduced and the abnormal meconium completely removed through a small ileotomy by a technique to be described later. The ileotomy was closed the bowel was replaced and the abdomen closed without drainage.

For the first four postoperative days the baby's course was rather stormy and she was maintained on parenteral fluids. Nasogastric suction was carried out during this period. On the second postoperative day a small amount of meconium was passed per rectum and from then on the baby had stools at normal intervals. Water was given by mouth on the fourth postoperative day and a day later an evaporated milk formula (1:3 plus 5 per cent cane sugar) was started. Pancreatin in 5 per cent solution was administered through the nasogastric tube until the baby was taking food per os. Pancreatin was then given per os in doses of 0.5 gram with each feeding a total of 3.0 grams daily.

Duodenal drainage was performed at the end of the third week in the hospital. Analysis revealed a tryptic activity of 2.0 units per cubic centimeter (the normal is 100 plus) confirming the diagnosis of cystic fibrosis of the pancreas associated with meconium ileus. At this time (at 3 weeks of age) the diet was changed to a formula containing protein milk powder 60 grams glucose 30 grams casein hydrolysate 6 grams, and water to make 720 cubic centimeters. The following vitamin supplements were also given: B complex 2 cubic centimeters twice daily, oleum percomorphum 12 drops once a day, ascorbic acid 50 milligrams once a day, and pancreatin was continued at a dose of 3.0 grams daily (0.5 grams per feeding or bottle).

Intramuscular penicillin was administered for the first 3 weeks to control infection. Sulfadiazine in prophylactic doses (0.1 gm. twice daily) was given for the remainder of the hospital stay.

The baby gained 400 grams in the first 3 weeks and after being changed to a protein milk formula continued to do well. She was discharged on the 52nd hospital day weighing 3,830 grams. She has been

Fig 1 a, Case 1 C F., at 1 month of age b at 15 months of age.

followed since in the out patient department and at the age of 26 months measured 86 centimeters in length and weighed 12,870 grams. Except for an occasional transitory upper respiratory infection she has had no difficulties (Fig 1).

CASE 2 C B A white female infant was born on the Sloane Maternity service of the Presbyterian Hospital on September 12 1945 weighing 3,510 grams. Pregnancy and labor were uneventful. One year previously the mother had given birth to an apparently normal male infant who soon after birth developed signs of intestinal obstruction and at autopsy was found to have meconium ileus associated with cystic fibrosis of the pancreas.

During the first 24 hours the baby appeared well but did not pass meconium and regurgitated the glucose taken by mouth. At 18 hours after delivery

Fig. 2. a, Case C B, 3 months of age; b, at 6 months of age.

there were palpable distended loops of gut in the lower abdomen and in the next 4 hours, the abdominal circumference increased from 33 to 37 centimeters. Rectal examination at this time revealed a small empty rectum.

The infant was transferred to the Babies Hospital. Nasogastric suction was started and parenteral fluids were administered. A roentgenogram of the abdomen on the following day showed loops of distended gut in the left upper quadrant. A diagnosis of intestinal obstruction probably due to meconium ileus was made and laparotomy was performed. Large dilated purple-hued loops of ileum contained in passed meconium. Through an enterotomy wound the gut was completely freed of this material.

Before closing the enterotomy 10 or 15 cubic centimeters of 5 per cent pancreatin in water was instilled into the ileum. The abdomen was closed about drainage. Parenteral fluids, nasogastric suction and general supportive measures, including blood and plasma infusions, were instituted immediately. For a few days there was a little relief of the abdominal distention, but on the third postoperative day meconium began to pass per rectum, and the baby had normal stools. Pancreatin was given every 4 hours like the nasogastric tube was in place, and the tube was clamped for 1 hour after each instillation. Upon removal of the tube pancreatin was continued per os and the baby started on karo water. On the fifth postoperative day an evaporated milk formula was begun. Duodenal drainage done on the tenth postoperative day revealed less than 1.4 units per centimeter of tryptic activity. This confirmed the diagnosis of cystic fibrosis of the pancreas associated with meconium ileus in this child and the diet was changed to protein milk powder 40 grams, glucose 20 grams, casein hydrolysate 6 grams, after 10 cubic centimeters. Vitamin supplements and pancreatin were given as in the preceding case and continued after discharge. At 8 weeks the diet was changed to hi pro 85 grams, glucose 20 grams, casein hydrolysate 10 grams, and water to 600 cubic centimeters. At 10 weeks of age egg yolk and strained string beans were added to the diet—one serving of each daily.

The remainder of the hospital stay showed a general improvement. On two occasions, the infant had episodes much like celiac crises which were marked by an increase in the number of stools, a sudden weight loss and vomiting. These episodes responded rapidly to administration of parenteral fluids and plasma. Penicillin was given for the first 2½ weeks, and again for a week when an upper respiratory infection was present. During the last 17 days, sulfadiazine was given as a prophylactic measure (0.1 gm twice daily).

Since discharge she has been followed in the outpatient department. She has had two additional admissions to the Babies Hospital for the treatment of bronchopneumonia—the first at about 9 months of age and the second at about 18 months. Both illnesses responded well to sulfadiazine given orally and to penicillin by aerosolization.

In spite of these two episodes she has grown well and gained regularly and now at 20 months of age, weighs 10,900 grams and measures 80 centimeters in length (Fig. 2).

CASE 3. A. F. A white male infant was admitted on August 18, 1946 at 10 hours of age after a normal delivery at another hospital. No abnormalities were noted at birth. He began to vomit bile-stained material within the first 4 hours and continued to do so until admission. No meconium was passed per rectum. A sibling had died 1 year previously with a similar clinical picture and was found at a topography to have meconium ileus with cystic fibrosis of the pancreas.

Fig. 3. Weight curves of Cases 1 and 2 compared with the normal mean.

Fig. 4. Height curves of Cases 1 and 2 compared with the normal mean.

Examination revealed a tense, distended abdomen and an empty hypoplastic rectum. Crepitation could be elicited in the left upper quadrant of the abdomen and a large mass could be appreciated running transversely across the abdomen. Three position roentgenograms revealed dilated upper small gut loops containing fluid levels. Because of the history of meconium ileus in the sibling and the above findings a diagnosis of meconium ileus was made. The operation was performed 30 hours after birth. The 20 hour preoperative period in the hospital was used for hydration and tube suction of the stomach.

The operation was performed through a right rectus incision and the diagnosis of meconium ileus was confirmed. The mass and crepitation noted on physical examination were due to a tremendously hypertrophied and dilated loop of upper ileum which had undergone a 360 degree volvulus and was gangrenous, but not yet perforated. This was resected and the remaining meconium completely removed by saline irrigation through a No. 16 catheter utilizing a pursestring suture around each of the cut ends of the gut. When the gut was completely empty of meconium, an end-to-end anastomosis was performed an inner layer of continuous No. 0000 and an outer serous layer of interrupted No. 0000 silk being used. The operative wound was closed in layers without drainage.

Summary of surgical pathology report. The specimen is a greatly dilated segment of small bowel 40 centimeters in length with a maximal diameter of 5.5 centimeters proximal to the site of a contracting twist of the gut. Microscopic examination shows early gangrene of the dilated portion.

Postoperatively the child was put in an incubator equipped for oxygen administration gastric suction was maintained and supportive treatment with saline, plasma, and blood was given. Penicillin (10,000 units) was given intramuscularly every 3 hours and 0.5 gram of pancreatin in solution was in-

stilled through the nasogastric tube and the tube clamped for 1 hour after each instillation. The child began to have bowel movements on the third postoperative day and was started on karo water on the fourth postoperative day. This was supplanted by formula on the sixth postoperative day. For the rest of his hospital stay the child received vitamins A, D and B complex and pancreatin 3 grams once a day. Sulfadiazine was started on the eighteenth postoperative day because of a few pulmonary rhonchi and continued until the time of discharge. On the fourth postoperative day a high protein formula for fibrocystic disease of the pancreas was initiated. The wound healed per primam. A duodenal drainage was done on the twenty-ninth postoperative day revealing only 5.2 units per cubic centimeter of trypsin in the duodenal secretions.

The child was discharged on the thirty-second postoperative day slowly gaining weight and free of pulmonary symptoms. He is being maintained at home on a high protein, high carbohydrate, low fat diet, and pancreatin. He was last seen on October 4, 1946 with a cough but no rales could be heard and the chest was clear on fluoroscopy. On October 22, 1947 he was reported as thriving although he had had several respiratory infections during the preceding year.

CASE 4. B. G. M. A male child 12 hours old was admitted with a history of vomiting bile-stained material shortly after birth and failure to pass meconium by rectum. The abdomen was noted to be distended at birth. Family history revealed that a sibling had died of an intestinal obstruction at 6 days of age. Examination revealed a markedly distended abdomen and an empty collapsed rectum. Roentgenograms revealed dilated upper small gut loops containing fluid levels. Small bubbles of air could be seen more distally. Because of these findings, a preoperative diagnosis of meconium ileus was made.

At operation this diagnosis was confirmed. However there were some marked variations in the pathological findings which could be recognized as diminishing the chances of successful intervention. The degree of hypertrophy of the upper ileum and the lower jejunum was much less than usual and the length of the atrophic ileum was three times what is usually seen. The impression of a more severe form of the disease was obtained. However all the abnormal meconium was removed in the usual manner and the abdomen closed without drainage.

Postoperatively the baby did not have any stools and died after 5 days with progressive distention, circulatory failure, and sclerema. No autopsy was obtained.

CASE 5 B G C. A female child 52 hours old was admitted with a history of vomiting and absence of stools since birth. The family history was negative. Examination revealed a baby who appeared dehydrated and feeble with a markedly distended abdomen and a small empty collapsed rectum. The skin had a decidedly icteric tinge. Roentgenograms showed dilated small gut loops containing fluid levels. We were unable to make a definite diagnosis although meconium ileus was strongly suspected.

After a 9 hour period of hydration and suction of stomach contents, the abdomen was opened and a typical meconium ileus with volvulus was found. The gut was easily cleared of abnormal meconium by the technique to be described and the abdomen closed without drainage.

Postoperatively the child seemed to be doing well but suddenly died at the end of the first postoperative day. Autopsy revealed a profuse peritonitis. Cultures of the meconium removed from the proximal and distal segments of ileum at operation both yielded a pure culture of *Escherichia coli*. Blood cultures before death also yielded *Escherichia coli*. Therefore, the cause of death was judged to be bacteremia and peritonitis due to *Escherichia coli*. Fibrocystic disease of the pancreas was found at autopsy.

CASE 6 N K. A white male infant 8 days old was admitted to Babies Hospital because of persistent vomiting and distention since birth and failure to pass meconium per rectum. This child was the result of the second pregnancy in this family the first ending in a miscarriage. Normal delivery occurred at another hospital.

Examination revealed a moderately dehydrated infant with a distended abdomen and a small empty rectum. Three position films of the abdomen showed dilated upper intestinal loops containing gas and some fluid. The lower abdomen showed only an opaque medium of water density containing occasional minute air bubbles. Because of this roentgen picture and the solid consistency of the abdomen by palpation as well as the small empty rectum, the diagnosis of meconium ileus was made.

Following a three hour period of hydration and nasogastric suction the abdomen was opened through a right rectus incision. In addition to meconium ileus

the patient had a 360 degree volvulus of a loop of upper ileum with impairment of circulation, but no appreciable gangrene. The volvulus was reduced and the abnormal meconium removed in the usual manner. The abdomen was closed without drainage.

Postoperatively the baby continued to be distended in spite of nasogastric suction and pancreatin every 6 hours. The stools were very scanty and ceased altogether on the third postoperative day. In spite of penicillin, streptomycin, and general supportive measures, the baby died on the fourth postoperative day.

Autopsy revealed that the probable cause of death was the devitalized loop of ileum that had been involved in the volvulus. It had remained devitalized and the mucosa was actually gangrenous. There was a marked peritoneal reaction around this loop. Cystic fibrosis of the pancreas was also confirmed at autopsy.

CASE 7 J H M. A male infant of 3 days was admitted with a history of vomiting and progressive distention since birth. Delivery was normal. The family history was negative with respect to pancreatic deficiency.

Examination revealed a moderately dehydrated infant with a hard distended abdomen and a small empty rectum. Roentgenograms showed large dilated loops of intestine with air fluid levels.

After 3 hours of nasogastric suction and hydration the patient was operated upon through a right rectus incision and a meconium ileus was found. There was no volvulus. The abnormal meconium was evacuated and the abdomen closed without drainage. Three grams of pancreatin in 4 milliliters of saline was inserted into the gut before closing the enterotomy.

The usual postoperative regimen of nasogastric suction, pancreatin saline plasma and penicillin was carried out and the course was uneventful. Bowel movements began on the first postoperative day and feeding was started on the third postoperative day. The wound healed per primam. Duodenal drainage revealed only 1.4 units per cubic centimeter of trypsin in the duodenal fluid.

The patient was discharged from the hospital on the 39th postoperative day on a high caloric, high protein low fat formula with 3 grams of pancreatin once daily.

No difficulties have been encountered during the 3 1/2 month period to the present.

CASE 8 P C. A white male infant was first seen at 24 hours of age with a history of persistent vomiting and increasing abdominal distention since birth. Normal delivery occurred at another hospital. The family history was noncontributory.

Examination revealed a moderately dehydrated baby with a markedly distended hard abdomen. Large, dilated, nontympanic loops of intestine could be palpated through the abdominal wall. The rectum was small and empty. Roentgenograms showed dilated upper intestinal loops filled with gas and fluid. No gas was seen in the rectum or colon.

After 4 hours of hydration and nasogastric suction the patient was taken to the operating room and the abdomen was opened through a right rectus incision. A typical meconium ileus was found with a mild volvulus in the upper ileum without circulatory impairment. The volvulus was reduced and the abnormal meconium removed in the usual fashion through an enterotomy. Three grams of pancreatin in 40 milliliters of saline was instilled before closing the enterotomy.

The postoperative course was uneventful. The infant began having bowel movements on the first postoperative day. The postoperative regimen included nasogastric suction with instillation of pancreatin every 6 hours penicillin streptomycin saline and plasma. Nasogastric suction was discontinued on the third postoperative day and feedings were begun. Trypsin was found to be almost absent from the duodenal juice in the third postoperative week.

In the 2 months following discharge, the patient did not do well because of recurrent pulmonary difficulties. At the time of preparation of this paper he was again in the hospital with a severe bilateral pneumonia for which tracheotomy was performed to facilitate suction of the bronchial tree. He died at the age of 3 months. Postmortem examination confirmed the diagnosis of cystic fibrosis of the pancreas. The ileum and colon were of normal dimensions throughout.

In reviewing these 8 cases we emphasize the fact that combined surgical and medical treatment is necessary. The literature reveals that the few cases of meconium ileus which have been successfully treated surgically have succumbed to subsequent respiratory complications of the type usually associated with pancreatic insufficiency resulting from cystic fibrosis.

Since the recognition of this syndrome in 1905 the longest reported postoperative survivals have been a few weeks or months. Our Cases 1, 2, 3, and 7 represent the first successful results to be reported.

SURGICAL CONSIDERATIONS

The main purpose of the surgical treatment of these patients is the complete removal of the abnormal meconium as quickly and as gently as possible. In order to do this, an accurate understanding of the presenting pathology is necessary. In all these cases approximately the distal half of the small gut is filled with abnormal material. This varies from semiliquid to extremely tenacious meconium in the lower jejunum and upper ileum and be-

Fig. 5 The external appearance of the intestine in typical meconium ileus.

comes gradually more desiccated in the more distal loops so that a segment of the terminal ileum which varies in length from 20 to 40 centimeters is filled with actual concretions. The concretions are hard greyish white and they make a perfect cast of the inside of the ileum.

The most striking abnormality is the hypertrophy and dilatation of the mid-ileum. This hypertrophy and dilatation begins usually in the lower jejunum and becomes maximal in the mid ileum and ends 20 to 40 centimeters from the ileocecal valve. The transition from the dilated portion of the ileum where the meconium is semifluid to the small thin walled terminal ileal segment containing the above described concretions is sometimes abrupt. The area of maximum hypertrophy and dilatation in the mid ileum will often measure 7 centimeters in diameter while the terminal segment averages approximately 1.5 centimeters in diameter. The large intestine in each case in the series was found to be empty, small and hypoplastic.

od between birth and operation was 52 hours death was due to *Escherichia coli* peritonitis and septicemia the presence of this organism in the gastrointestinal tract within 2½ days of the time of birth was further confirmed by cultures of the meconium at operation. A certain period of observation is necessary to rule out the possibility of transient meconium plugs causing temporary obstruction. It also allows time for decompression of the stomach with a tube under constant suction and the correction of the disturbed water and electrolyte balance. The decision for operative intervention at the end of this time depends upon the absence of gas in the colon as seen by roentgenogram. In the presence of colonic gas further delay is justified.

Another very important consideration in these cases is the association of meconium ileus with volvulus. Because of the tremendous hypertrophy and elongation of the small gut before birth in this disease it is a common experience to find a loop twisted upon itself resembling a volvulus. There is one important difference however in that the gut wall in the involved loop is markedly hypertrophied a fact which indicates to the surgeon that the primary pathology is more distal. The presence of this phenomenon was observed in 5 of our patients.

In evaluating the causes of death in the 3 infants who did not survive the postoperative period we find that one had a very severe form of the disease with an unusually long hypoplastic segment of terminal ileum and minimal hypertrophy proximal to this. The other deaths we feel certain were due to our failure to resect devitalized gut that had been involved in a volvulus. The demands on this gut in the postoperative period to propel material through underdeveloped terminal ileum and colon require that it be healthy. By devitalization we mean any loop that appears to have lost its full powers of peristalsis. Since the terminal ileum and entire colon are very thin walled and as proximally the effect of an ordinary lead pencil must of the propulsive power must come from the hypertrophied small gut proximal to this. If a loop with poor peristaltic power is allowed to remain it will inevitably prove fatal to the patient. In Case

3 in which the loop of gut involved in the volvulus was actually gangrenous resection plus removal of abnormal meconium was quite successful.

The three most important surgical principles to be kept in mind are (1) complete evacuation of abnormal meconium (2) appreciation of the fact that meconium ileus may be the underlying cause of a volvulus in the neonatal period and (3) resection of all devitalized gut.

MEDICAL MANAGEMENT

The reports of Andersen (1, 2) indicate that the earlier the diagnosis of pancreatic insufficiency is made the better is the prognosis for prevention of respiratory disease and for survival. The outlook is best if the diagnosis can be made and proper therapy commenced before the onset of respiratory disease.

In the 4 surviving infants operated upon at Babies Hospital the diagnosis of pancreatic fibrosis was suspected from the first because of the findings at operation. As soon as the condition of the infants allowed duodenal drainage was performed and analysis of the secretions for trypsin carried out. The results indicated the presence of pancreatic insufficiency in all cases confirming the diagnosis of cystic fibrosis of the pancreas.

Because of the previously known association of meconium ileus with cystic fibrosis of the pancreas the dietary changes advocated by Andersen were instituted even before confirmation of diagnosis had been obtained by demonstration of low trypsin activity in duodenal juice. All patients were started on a protein milk formula fortified with glucose and casein hydrolyzates the exact composition of the diet for each child is described in the case reports. Later hipro was substituted for protein milk although the latter could well have been continued. Since discharge from the hospital various alterations have been made to the diets and at present each child of suitable age is receiving strained fruit juices (not cheese fruits vegetables fello junket etc.) and meat (boiled broiled or roasted with all visible fat removed). The formulae are continued with the proportions of milk and sample 1 as increased to bring the caloric value up to the individual child's requirement (Table II).

sis of meconium ileus in a newborn infant with intestinal obstruction

5 Five of the 8 patients coming to operation were successfully relieved of intestinal obstruction. The oldest of the survivors is now more than 2 years old. The prognosis of the survivors is dominated by the underlying pancreatic disease

CARCINOMA OF THE BLADDER WITH BONE METASTASES

A Report of 8 Cases

HERMAN L. KRETSCHMER, M.D. F.A.C.S. and J. H. McDONALD, M.D. Chicago, Illinois

THE old idea that bone metastases secondary to carcinoma of the bladder are of rare occurrence seems still to prevail. In a previous communication one of us (H.L.K.) reported 3 cases and called attention to the fact that this condition occurs more frequently than is appreciated, and that it may occur with small papillary tumors that appear to be simple papillomas. As early as 1854, Schraut called attention to the fact that bone metastases do occur in cases of carcinoma of the bladder.

Articles in the older as well as in the recent literature, generally dealt with the report of a single case. The renewed interest in this subject has been followed by articles that deal with a series of cases. Many of these cases are reported by roentgenologists and orthopedists in articles dealing with the general subject of bone metastases and unfortunately contain little or no detailed information. Among the urologists who have reported a series of cases may be mentioned Burkland and Leadbetter Colston and Leadbetter Graves Jewett, Judd, Kretschmer Sutherland, and Turner and Jaffe.

In the older textbooks the subject received scant attention. However some authors, like Geraghty Herman, and Hinman feel that bone metastases are an important and frequent finding. Beer Colston Geschickter Judd Kretschmer Lemaitre, Turner and Jaffe, and many others, are of the opinion that the condition is more common than is generally believed.

The report of the Carcinoma Registry of the American Urological Association in 1934 showed the incidence of bone metastases to be 3.7 per cent of the 902 bladder tumors then recorded. The present paper is based on a series of 8 cases and a review of the literature.

CASE REPORTS

CASE 1. L. C. M., male, aged 73 years, entered the Presbyterian Hospital on the service of H. L. K.

July 3, 1946. On July 8, 1946 a transurethral resection of the prostate and a bladder tumor was performed by Dr. N. J. Heckel. The pathological examinations revealed benign hypertrophy of the prostate and papillary carcinoma of the bladder. The patient was readmitted to the hospital on October 15, 1946 with the complaint of gross hematuria, with passage of blood clots of 4 days' duration.

Physical examination was essentially negative except for bilateral inguinal hernias. Rectal examination revealed an enlarged prostate grade 1/4, soft and smooth with no signs of carcinoma. The blood count and Kahn test were normal, the nonprotein nitrogen was 53 milligrams per cent and the urinalysis showed albumin 2+ and a grossly bloody urine.

Suprapubic cystostomy was performed on October 26, 1946 (H.L.K.) because of profuse hemorrhage. At operation a large ulcerating tumor located on the right lateral wall was found. The bladder was packed with gauze. Biopsy report stated papillary carcinoma (Fig. 1). Convalescence was uneventful and he was discharged November 16, 1946, with permanent suprapubic catheter drainage.

On June 15, 1947 he developed a painful swelling in the left clavicle. Ten days later in attempting to turn himself he heard a snap in the left clavicle, which was followed by severe pain. His physician made a diagnosis of pathological fracture due to metastatic carcinoma of the clavicle. The patient was bedfast at home and unable to have a roentgen-ray examination but the clinical diagnosis seems perfectly obvious.

CASE 2. L. C. H., male, aged 60 years, entered the Presbyterian Hospital on the service of Dr. E. J. Berkholder. In June, 1948 he underwent elsewhere a partial resection of the bladder for tumor with reimplantation of the left ureter into the bladder. The ureter became obstructed at the site of implantation and a left nephrectomy was done. In January 1949 a transurethral resection of the prostate was done elsewhere. Two months before admission patient developed severe bilateral sacroiliac pain which radiated into the legs. The urinary symptoms were frequency nocturia, dribbling and weakness of the urinary stream.

Physical examination revealed a left lumbar and a suprapubic scar. Severe pain was noted on pressure over the fifth lumbar vertebra. Rectal examination revealed a normal prostate. The blood count was normal. The urinalysis showed albumin 2+ with many red blood and pus cells.

RAY are indebted to Dr. Theodore J. Smith for notes on the course of the patient's illness after he left the Presbyterian Hospital.

Roentgen ray examination March 15 1943 revealed destruction of the 4th lumbar vertebra and the upper border of the sacrum compatible with metastasis. A second roentgen examination on April 26 1943 revealed destruction of the anterior border of the second and fourth lumbar vertebrae with some compression of the fourth lumbar vertebra compatible with metastasis (Fig 2).

On April 6 1943 a cordotomy was performed by Dr. A. Verbruggen at the level of the third segment, for the relief of severe pain.

The patient continued his narcotic requirements gradually failed and died on September 30 1943.

Autopsy September 30 1943 revealed a papillary carcinoma of the bladder (Fig 3) retrograde tumor implantations in the dilated left ureter extensive metastatic carcinoma of the left renal fossa extensive metastatic carcinoma of the lumbar spine (Fig 4) metastatic carcinoma of the sacrum and lower thoracic vertebrae metastatic carcinoma of the liver lower lobe of right lung pulmonary hilar upper mediastinal and perihilar lymph nodes.

CASE 3 S. B. female, aged 50 years entered the Presbyterian Hospital on December 31 1945. One year ago she developed hematuria frequency nocturia urgency and dysuria.

Blood examination blood chemistry Wassermann roentgen ray examination and intravenous pyelogram all were negative. The urinalysis showed a trace of albumin and the sediment showed red blood cells. The cystoscopic examination (H.L.K.) revealed five papillary tumors on the floor of the bladder. They were resected and the bases fulgurated. Pathological report showed papillary carcinoma of the bladder (Fig 5).

The patient re-entered the hospital in June and October 1946 and further resection and fulguration of bladder tumors was carried out.

Operation (H.L.K.) was performed December 16 1946. It consisted of suprapubic cystostomy with wide resection of bladder wall and tumor. Pathological report showed papillary carcinoma of the bladder. Operation for closure of the fistula (H.L.K.) was carried out on January 27 1947.

On March 17 1947 patient complained of pain in her right lower chest. Roentgen ray examination revealed a pathological fracture of the right ninth rib anteriorly (Fig 6) a compression fracture of the upper border of the third lumbar vertebra and multiple areas of bone destruction involving the pubic bones and the upper end of the right femur compatible with metastases (Fig 7). A chest film revealed small areas of increased density scattered throughout both lung fields suggesting metastasis.

Deep roentgen ray therapy was instituted. Her convalescence was slow requiring large quantities of narcotics for relief of pain. She was discharged on April 17 1947 and died 3 weeks later. No autopsy was made.

CASE 4. M. T. male aged 58 years entered the Presbyterian Hospital on July 8 1936. In 1934 he underwent elsewhere a transurethral fulguration of

Fig. 1. Case 1. Typical papillary carcinoma of the bladder $\times 80$.

a bladder tumor and a litholapaxy. First admission to the Presbyterian Hospital was in May 1936 when a transurethral resection and fulguration of a bladder tumor was done (H.L.K.). Microscopic report showed papillary carcinoma of the bladder (Fig 8). One month prior to his present admission patient developed severe pain in the right hip and thigh frequency of urination nocturia attacks of hematuria and severe dysuria.

Physical examination revealed scars over the right upper and lower quadrants. A hard mass fixed to the symphysis pubis extended 4 fingers breadth above the symphysis pubis. Palpation produced severe pain. Enlarged inguinal glands were noted on the right side. The rectal examination was negative.

The blood count was normal. The urinalysis showed 10 000 pus cells per cubic millimeter and 800 erythrocytes per cubic millimeter. Culture of the urine showed *Bacillus coli communis*.

Roentgen ray examination revealed destruction of the right superior and inferior rami of the pubis with thinning of the left pubis compatible with bone metastases (Fig 9). The patient was given deep roentgen ray therapy and discharged from the hospital in fair condition on July 13 1936. The patient died 4 months later.

Fig. 1. Case 1. Note destruction of the second and fourth lumbar vertebrae.

Fig. 2. Case 2. Typical papillary carcinoma of the bladder. X70.

CASE 5. M. A. C. I. male, aged 53 years, entered the Presbyterian Hospital on December 23, 1946. In February, 1946, a transurethral resection with fulguration of bladder papilloma was done (H. L. K.). Biopsy report revealed papillary carcinoma of the bladder (Fig. 10). In May, 1946, and in October, 1946, further transurethral resection and fulguration of bladder papillomas were carried out (H. L. K.). Biopsy report, October, 1946, revealed papillary carcinoma of the bladder with invasion of granulation tissue and smooth muscle.

Four days prior to admission patient developed gross hematuria, frequency, nocturia and dribbling at the end of urination.

Roentgen ray examination, intravenous urograms and blood count were negative. Urinalysis showed 50 red blood cells per cubic millimeter.

Operation (H. L. K.) consisted of transurethral fulguration of an elevated area at the site of previous resection. Patient was discharged in good condition on December 25, 1946.

In the middle of March, 1947, the patient injured her right leg just below the knee. Six weeks later a swelling developed at the site of injury. A roentgenogram showed a circumscribed osteolytic destruction in the tibia just below the tibial tuberosity (Fig.

11). She was operated upon elsewhere and the cyst was curetted. The tissue removed was sent to one of us. The diagnosis was metastatic papillary carcinoma (Fig. 12) secondary to papillary carcinoma of the bladder. Subsequent roentgen ray studies showed two lesions in the left lower tibia. The patient is now bedridden and failing rapidly.

CASE 6. T. G. T., male, aged 45 years, entered the Presbyterian Hospital on September 21, 1931. On November 6, 1933, a suprapubic cystostomy was performed elsewhere for the removal of a tumor of the bladder. Pathological diagnosis was papillary carcinoma of the bladder. He was readmitted to the same hospital because of multiple abscesses of the left kidney and postoperative obstruction of the left ureter. On January 15, 1934, a left nephrectomy was performed.

Seven months before admission patient developed severe pain in the left hip and thigh, requiring narcotics for relief. He cannot walk without the aid of crutches.

Physical examination revealed a suprapubic and left lumbar scar. Rectal examination was negative. The left lower extremity showed marked muscular atrophy.

We are indebted to Dr. P. J. Sausal for the information of the patient's subsequent course.

Fig 4. Case 3. Metastatic papillary carcinoma of the lumbar spine $\times 80$.

Fig 5. Case 3. Typical papillary carcinoma of the bladder $\times 80$.

Fig 6. Case 3. Note pathological fracture of the right ninth rib.

phy and pain on pressure over the left thigh and hip. The blood count and blood Kahn were normal. Blood chemistry was normal. The urine contained 85 pus cells and 300 red blood cells per cubic milli-

Fig 7. Case 3. Note multiple areas of destruction in the pelvic bones and right upper femur.

Fig. 8. Case 4. Typical papillary carcinoma of the bladder. $\times 80$.

Fig. 9. Case 5. Typical papillary carcinoma of the bladder. $\times 80$.

meter and on culture showed growth of *Bacillus coli communis*.

Roentgen ray examination revealed marked destruction of the left pubis, the left lower ischium

Fig. 10. Case 4. Note destruction of the right pubic bone.

and the lower trochanter of the left femur with a fracture through this area. There was general thinness of the left ilium with very tiny areas of destruction. Findings were compatible with metastatic carcinoma (Fig. 13).

Cystoscopic examination (H.L.K.) on September 22, 1934 and September 26, 1934, revealed a normal bladder. The patient was discharged on September 27, 1934, his condition unchanged.

CASE 7. C. B. female, aged 61 years, entered the Presbyterian Hospital on April 6, 1928. She had had salpingo-oophorectomy in 1908 and a gall-bladder operation in 1920, performed elsewhere.

One year prior to admission she had had an attack of gross hematuria. This was followed by frequency, nocturia, urgency and suprapubic pain. She has had 11 subsequent attacks of hematuria, one 6 months ago and one 2 weeks ago.

Physical examination revealed a mild cervical ectropathy, the scars of her previous operations and marked tenderness over the pubic bones. The blood count and Wassermann were negative. The blood nonprotein nitrogen was 40.5 milligrams per cent and the urea nitrogen was 24 milligrams per cent. The urinalysis showed 100,000 pus cells, 200 red blood cells per cubic millimeter and a few granular casts. Urine cultures were sterile.

Fig 11 Case 5 Note the circumscribed destruction in the proximal end of the tibia.

Cystoscopic examination revealed a tumor of the bladder with areas of superficial necrosis.

Roentgen ray examination revealed a destructive process of the pubis on either side of the symphysis compatible with bone metastasis.

On April 11 1928 a suprapubic cystostomy was done (H.L.K.). The tumor had extended beyond the bladder. Surgical diathermy was used and pieces of tissue were excised for diagnosis. Microscopic diagnosis papillary carcinoma of the bladder. Patient was discharged from the hospital on July 3 1928 and died December 2 1928.

CASE 8 R. A. F. male, aged 53 years entered the Presbyterian Hospital on October 19 1946. Elsewhere in 1937 a suprapubic cystostomy was performed for removal of papilloma of the bladder. Elsewhere in 1938 a transurethral resection of the prostate was performed. In 1943 a left orchiectomy was performed because of abscess. In November, 1944 at the Presbyterian Hospital a transurethral resection of the prostate was done with resection and fulguration of small papillary tumors on the trigone (H.L.K.). Pathological report was benign hyperplasia of the prostate and papillary carcinoma of the bladder (Fig 14). In November 1945 incision and drainage of a penurethral abscess (H.L.K.) was done. On March 18 1946 a suprapubic cystostomy was done because of persistent hematuria, frequency, urgency and pain. There were no papillomas in the

Fig 12 Case 5 Metastatic papillary carcinoma of the right tibia. X80

bladder but just distal to the vesical orifice papillomatous growths were removed for biopsy which showed papillary carcinoma. On March 28 1946

Fig 13 Case 6 Note destruction of the left pubis, ischium and lesser trochanter with a fracture through the latter structure.

Fig. 14. Case A. Transitional papillary carcinoma of the bladder. $\times 80$.

Cytologic microscopic examination showed the bladder to be normal. Examination of the prostatic urethra showed many small papillomas which were resected and fulgurated (H. L. K.). Pathological report was papillary carcinoma.

Fig. 6. Case 8. Note destruction of the fifth lumbar vertebra.

On present admission to hospital patient complained of hematuria and severe pain in the lumbar region radiating into the left leg.

Physical examination revealed a suprapubic fullness. Rectal examination showed a normal prostate. The blood count was normal except for mild anemia. Blood nonprotein nitrogen was 39 milligrams per cent. Urinalysis showed a grossly bloody urine with albumin $1+$ and pus cells 8 to 10 per cubic millimeter.

Roentgen ray examination October 23, 1948, showed complete destruction of the fifth lumbar vertebra and an area of destruction involving the superior ramus of the left pubic bone (Figs. 15 and 16).

After he left the city, patient suffered rapidly developing paralysis of both lower extremities. He had extreme pain in the lumbar and sacral areas and throughout the distribution of both sciatic nerves. He died in March 1947.

The cases are summarized in Table I.

AGE AND SEX

The age of the patients in our series varied from 45 to 73 years with an average age of 59.5 years. There was no apparent relation

Fig. 5. Case 8. Note destruction of the superior ramus of the left pubic bone.

TABLE I.—SUMMARY OF CASES

Case Name	Age	Sex	Duration	Urinary symptoms	Metastatic symptoms	Pathological diagnosis	Site of metastases	Type of bone lesion	End results
L.C.M.	33	M	6 yrs.	Hematuria Frequency	Pain in left clavicle	Papillary carcinoma	Left clavicle	N-ray	Falling rapidly
L.C.H.	60	M	9 mos.	Frequency Nocturia Dribbling	Pain in sacro- coccygeal area	Papillary carcinoma	nd and 4th lumbar vertebrae; lower dorsal vertebrae sacroca	Osteolytic	Died
S.B.	51	F	3 yrs.	Hematuria Frequency	Pain in chest Pain in low back	Papillary carcinoma	Rt. 9th rib and lumbar vertebra rt. femur pubic bones	Osteolytic	Died
M.T.	48	M	3 yrs.	Hematuria Frequency	Pain rt. hip Pain rt. thigh	Papillary carcinoma	Rt. and left pubic bones	Osteolytic	Died
M.A.C.	58	F	37	Hematuria Frequency	Pain rt. lower leg Swelling rt. low leg	Papillary carcinoma	Right tibia, left tibia	Osteolytic	Bedfast and fall- ing rapidly
T.G.T.	45	M	3 yrs.	Hematuria	Pain left hip Pain left thigh	Papillary carcinoma	Left femur left pubis, left humerus left ischium	Osteolytic	Died
G.H.	61	F	37	Hematuria Frequency	Suprapubic pain	Papillary carcinoma	Right and left pubic bones	Osteolytic	Died
R.A.F.	53	M	9 yrs.	Hematuria Frequency	Pain lumbar spine and left leg	Papillary carcinoma	4th lumbar vertebra left pubes	Osteolytic	Died

ship between the age at the onset of the symptoms and longevity. Geschickter stated that females are more prone to develop bone metastases than are males. This has not been our experience in our series there were 5 males and 3 females.

TYPE OF BLADDER TUMOR

The primary tumors varied from small benign appearing papillomas to large ulcerating tumor masses. The size of the tumor apparently had little relationship to the formation of skeletal metastases. This is also noted by Nicholls who reported a case in which neither the primary bladder tumor nor the metastatic bone lesion showed evidence of malignancy though both were identical in type and structure. Rathbun and Kretschmer also had noted skeletal metastases secondary to small benign appearing primary tumors. In our cases the primary bladder neoplasm was papillary carcinoma.

In one case (Case 6) the bladder tumor had been treated by segmental resection. There was no evidence of tumor upon two cystoscopic examinations. The patient came to the hospital because of pain due to the skeletal metastases. In Case 8 the bladder was free of papillary tumor but multiple small papillary tumors were found in the prostatic urethra.

URINARY SYMPTOMS

Hematuria was present in 7 of our 8 cases and varied from slight intermittent bleeding to continuous bleeding with clot formation. In one case no statements relative to hematuria were noted in history. Frequency and nocturia, dysuria and pain were present in 7 of our 8 cases. Urinary symptoms lasted from 9 months to 9 years. In 4 cases the symptoms were present for less than 1½ years.

PAIN DUE TO METASTASES

In 2 instances (Case 2 and Case 6) pain due to the skeletal metastases was the symptom that brought the patient to the hospital. During the early course of the disease the pain was described as rheumatic in type. The pain rapidly became severe and excruciating so that all of the patients required morphine for relief. In Case 5 of our series and in the case reported by Ingraham surgery was performed on the skeletal metastases only to find that they were secondary to a bladder tumor. In the cases reported by Greenfield, Wells and Copeland the symptoms due to the metastatic lesion was the first indication of the patient's illness.

ROENTGEN RAY FINDINGS

In 7 of our 8 cases the metastatic lesions were osteolytic in type. In 1 case (Case 1)

Fig. 4. Case 8. Transitional papillary carcinoma of the bladder. $\times 80$.

cystoscopic examination showed the bladder to be normal. Examination of the prostatic urethra showed many small papillomas which were resected and fulgurated (H.L.K.). Pathological report was papillary carcinoma.

Fig. 5. Case 8. Note destruction of the fifth lumbar vertebra.

On present admission to hospital patient complained of hematuria and severe pain in the lumbar region radiating into the left leg.

Physical examination revealed a suprapubic fistula. Rectal examination showed a normal prostate. The blood count was normal except for mild anemia. Blood nonprotein nitrogen was 39 milligrams per cent. Urinalysis showed a grossly bloody urine with albumin $1+$ and pus cells 8 to 10 per cubic millimeter.

Röntgen-ray examination October 23, 1946 showed complete destruction of the fifth lumbar vertebra and an area of destruction involving the superior ramus of the left pubic bone (Figs. 15 and 16).

After he left the city, patient suffered a rapidly developing paralysis of both lower extremities. He had extreme pain in the lumbar and sacral areas throughout the distribution of both sciatic nerves. He died in March 1947.

The cases are summarized in Table I.

AGE AND SEX

The age of the patients in our series varied from 45 to 73 years with an average age of 59.5 years. There was no apparent relation

*Reinstitutions of the same patient with the same source of bleeding are not included in this tabulation.

sification are (1) the presence of syncope or shock as evidenced by sweating, fainting, cold clammy extremities, hypotension, and tachycardia, (2) the lowest hematocrit level recorded, and (3) the number of transfusions required to stabilize the circulation. Based upon these criteria, a rough estimate of the amount of blood lost may be made (Table VI).

A moderate hemorrhage is one in which the loss of blood ranges from 500 to 1,000 cubic centimeters. Such patients have melena or ematemesis and occasionally faint at the beginning of the illness, but they do not show evidence of syncope or hypotension when reaching the hospital. The hematocrit is above 30; transfusions are rarely indicated. Emergency surgery is never indicated.

In group 2, severe compensated, the loss of blood is serious, amounting to as much as a liter in 24 hours, but the rate of bleeding is sufficiently slow so that with the benefit of occasional transfusions syncope or collapse does not occur after the patient has entered the hospital and the circulation has become stabilized. Such patients may continue to bleed for several days as evidenced by bloody stools. They may develop azotemia and abdominal distention but they always maintain a good circulatory state. About 30 per cent of

*Cor pulmonale

these patients require one or more transfusions. They are not candidates for emergency surgery.

The patients in group 3, severe uncompensated, are serious problems. They lose blood at a rate of a liter or a liter and a half in 24 hours and may continue to do so for several days. They not only have a history of syncope at the time of onset but usually are in shock at the time of admission. However, they respond well to transfusions and once stabilized by an initial transfusion of 1 or 2 liters do not again develop syncope or hypotension. They often continue to bleed steadily as evidenced by tarry stools, hematemesis, and a falling hematocrit but provided they are transfused at rates not exceeding 1,500 cubic centimeters daily they always appear to be in a good circulatory state. The indications for transfusions are continued bleeding but without a fall in blood pressure, weakness, faintness, sweating, or collapse. Although these patients recover without an emergency operation, they require the closest supervision by both internist and surgeon for at any moment the rate of bleeding may increase sufficiently to place them in the fourth or exsanguinating group of cases.

Under exsanguinating hemorrhage are placed those patients who not only have evidence of marked syncope and shock but who after transfusions of a liter or two fail to maintain a stable circulation despite continued transfusions of not more than 500 cubic centimeters every 8 hours. Characteristically these patients have repeated episodes of sweating, faintness, and hypotension despite liberal

transfusions. There may be sharp falls in the hematocrit despite transfusions but signs of syncope or shock are of more value than the exact level of the hematocrit. Repeated hematemesis and uncontrollable pain are often valuable contributory signs but these may be absent and are of less significance than syncope. The one reliable finding is failure to maintain a stable circulation despite transfusions which amount to about 500 cubic centimeters every 8 hours. It is our belief that these are the patients upon whom surgery must be employed.

It is obvious that in classifying patients according to this scheme experience and sound clinical judgment are of the greatest importance. Although a rate of hemorrhage of over 500 cubic centimeters in 8 hours has been set as the dividing line between a severe uncompensated and an exsanguinating hemorrhage the actual amount of loss is of less importance than the patient's reaction to it. *Recurrent syncope is the most valuable single sign.* In appraising these patients the closest co-operation between medical and surgical services is necessary. It is recommended that a bedside team of internist and surgeon follow from the moment of hospitalization every patient in whom emergency surgery may be considered.

The mortality from bleeding peptic ulcer at the Peter Bent Brigham Hospital for the last 7½ years is shown in Table II. During this period there were 163 patient admissions for this complaint, representing 141 individual patients. (Each hemorrhage has been included in computing the mortality. If a patient bleeds at widely separated intervals in different hospital admissions, each episode must be regarded as a separate and distinct risk to life.) Of the 163 hemorrhages, 137 were from duodenal ulcer with 6 deaths, 15 were from gastric ulcer

with 4 deaths, 9 were from jejunal or marginal ulcer and 2 from a combination of gastric and duodenal ulcer. There were 125 males and 38 females and in 74 instances, or roughly 45 per cent, the age of the patient was 50 years or more. Under medical management there were 7 deaths in 154 cases, 4.5 per cent. Among the 9 patients undergoing emergency operation, there were 3 deaths. The hospital mortality rate was 6.1 per cent.

A somewhat different picture is obtained when the cases are classified according to the severity of the hemorrhage (Table III). It can be seen that 8 of the 10 deaths occurred in the exsanguinating group. The 9 deaths in the severe compensated group were not solely the result of hemorrhage. In the medical case, a comparatively small hemorrhage was the final precipitating cause of death in a patient with severe cor pulmonale. The surgical death in this group occurred as a consequence of an operation which by our present standards was ill advised and was carried out without adequate preoperative preparation. Two points are obvious: the fatal hemorrhages are of the rapid or exsanguinating type and in this group the results of surgery are at least as good if not better than medical management. It is our opinion based on a review of the records that the surgical recoveries represent pure salvage, that is, the patients would not have recovered without operation. Moreover among the patients who died under medical management, there are several who in retrospect appear to have been better risks for surgery than some of the patients in whom successful operations were performed.

Table IV analyzes the age factor and deaths in the entire series, in the severe uncompensated and in the exsanguinating groups.

TABLE VI.—A CLASSIFICATION OF CASES ACCORDING TO SEVERITY OF THE HEMORRHAGE

	Syncope or shock in hospital	Hematoctrit (or equivalent)	Transfusion	Estimated rate of blood loss
Moderate	None or slight	5 +	No	500 cc. \pm Total
Severe compensated	None or slight	50 less	Frequent (50%)	500-1000 c. per 24 hrs.
Severe uncompensated	Marked	30 or less	Usual (20%) response good	1000-500 c.c. per 4 hrs.
Exsanguinating	Profound, \pm recurrent	30 or less	Massive response uncertain	500 c.c. \pm per 24 hrs.

Although there is a higher proportion of deaths in patients 50 years of age or more it is less pronounced than might be expected in the more serious bleeders in exsanguinating hemorrhage considered alone there were 2 deaths in 5 patients under 45 and 6 deaths in 8 patients 50 or more. The point to bear in mind in connection with older patients is that they are more likely to develop an exsanguinating hemorrhage than younger patients. An apparently mild hemorrhage in an older patient deserves closer watching on this account. But older patients who do not have an exsanguinating hemorrhage have just as good a chance to get well on conservative management as the younger ones. To put it another way, the fact that a patient is over 50 years of age is not an indication for prompt surgery. Indeed quite the contrary, the older the patient the more desirable it is to avoid unnecessary surgery. But old age is a warning that there is greater

danger of an exsanguinating hemorrhage. If it develops surgery is necessary regardless of age. Thus the operative indication is not the age of the patient but the rate of the bleeding.

There is one type of patient for whom immediate surgery should be considered even though the hemorrhage is thought not to be exsanguinating. Every clinic has patients being followed medically for peptic ulcer who have bled in the past and in whom one more hemorrhage will be sufficient cause to recommend interval surgery. If such a patient should present himself in good condition with in a few hours of the onset of a hemorrhage a strong point can be made out for transfusion and immediate operation not only to check the bleeding but also to provide the corrective subtotal gastric resection. This combines as it were the otherwise separate risks of the hemorrhage and the interval operation. If such a patient is seen late in the course of a

FIVE YEAR END-RESULTS OF IRRADIATION THERAPY OF CANCER OF THE CERVIX UTERI AT THE MEMORIAL HOSPITAL

EQUINN W MUNNELL, M.D., and ALEXANDER BRUNSCHWIG M.D., F.A.C.S.,
New York, New York

A REPORT of the five year end results in 1 072 cases of primary carcinoma of the cervix in patients treated at Memorial Hospital during the period of 1934-1941 inclusive follows. These data were compiled for publication by the League of Nations Health Organization in its first report since 1941. In that year its last report presented a statement of results obtained in 1933 and previous years with radiotherapy in cancer of the uterine cervix at 17 different institutions in the United States, the British Isles, and the continent of Europe. Further collection of data was interrupted by the war but this is now being resumed under the editing direction of Professor J. Heymann of the Radiumhemmet in Stockholm.

The data in the tables in this paper are presented in the manner required by the League of Nations Health Organization. Only patients with cancer of the cervix uteri (including primary carcinoma of the stump) are included and these are instances in which the treatment carried out was entirely radiological. Only primary cases are included; patients having recurrent cancer following radiological treatment elsewhere are omitted. Precancerous conditions are excluded as are also sarcomas and malignant mixed tumors. All patients examined whether treated or not are included. Notation is made of those patients lacking microscopic verification of disease. To be classified as 'cured' the patient must be alive after 5 years or more and free from evidence of disease after treatment. Other requisites of the organization are made but the above are the essential ones.

It was felt that these figures comprising a large series of patients (1 072) should be made

available to American readers simultaneously with their presentation to the League of Nations Health Organization for publication. The data also suggest further discussion of the treatment of cervix carcinoma.

METHODS OF TREATMENT

Treatment during these years involved different techniques of external roentgen therapy together with a fairly constant method of radium application to the uterus. There was the massive dose technique of pelvic roentgen therapy in which the patient received 750 roentgens at a single treatment to each of four pelvic fields, 50 centimeter target skin distance, 200 kilovolts, 0.5 millimeter copper filtration. Also there was the "divided dose" technique in which the patient received 12 treatments of 200 roentgens each to each of six fields, 70 centimeter target skin distance, 200 kilovolts, 0.5 millimeter copper filtration. The pyramidal dose technique was a variation of the latter in which the number of roentgens per treatment was gradually increased. The superiority of the "divided dose technique" became evident after comparative study of the two methods (1).

External roentgen therapy was the supplement to radium application to the uterus in the form of a 'cervix tandem' to deliver 3 000 milligram hours of radium within the cervix and also by means of a vaginal "bomb" applicator to deliver 1,500 milligram hours against the cervix.

RESULTS

As already mentioned, the tables are presented in the form in which they are submitted to the League of Nations Health Organization. Table I presents the total number of patients with primary cancer examined in these

TABLE I.—PATIENTS EXAMINED AT THE CLINIC

years with further division into those treated and those not treated. Of the 1,072 patients examined 96.7 per cent or 1,037 were treated. Reasons for nontreatment are stated.

Table II presents the total number of patients treated in each year with breakdown into the four stages of the League of Nations anatomical classification. It is interesting to note that in the early years of this series the greater proportion of patients were in the more advanced stages of disease and that this situation tended to reverse itself in the later

years. This presumably represents the increasing cancer consciousness of the lay public and referring physician. This breakdown into stages undoubtedly incorporates some degree of error since it was necessary in compiling these statistics to change the old method of classification used at Memorial Hospital to that system suggested by the League of Nations. This possible error also affects the results of cures according to the different stages and will be mentioned again when the last four tables are discussed.

Total	37	297						1				1030					7					26				

Table III presents the number of patients alive without evidence of disease after a period of observation of at least 5 years and also those alive after this time but not cured. Columns 6 and 7 in this table contain those patients lost for follow up examination and those who died from some other cause both latter types of patient were considered *not* cured in computing 5 year end results.

Table IV presents the overall end results for at least 5 years without breakdown into stages of extent of cancer. It is the most important table. The absolute cure rate (column 5) is computed on cures per total number of

patients examined regardless of whether or not treatment was given. The relative cure rate (column 6) is based on cures per total number of patients actually treated. For the 1037 patients in all 4 stages actually treated the 5 year overall relative cure rate was 28.6 per cent.

In examining the relative cure rate by years one is immediately struck by the maintenance of an almost constant level of overall cure rates for these 8 years. There was no tendency for them to rise. This plateau tendency prevailed in spite of some increase of patients with the earlier stages of the disease.

Tables V VI VII and VIII present the relative cure rate by extent of disease according to the League of Nations anatomical classification stages I II III and IV respectively. The decrease in cure rate with increase in extent of disease is obvious. No stage IV patient was ever cured. The data show a rather striking uniformity of results obtained between the years 1934 and 1941 i.e. 52 to 62 per cent for stage I (with the exception of 2 years when the results were 47.1 and 45.7 per cent. For the 200 stage I cases in which patients were treated over the 8 year period the relative cure rate was 53.0 per cent (Table V). The apparent peaks in 1937 and 1938 lose significance when it is noted that only 39 stage I

patients were treated in these 2 years. For stage II the results were 24 per cent to 30 per cent except for 3 years when the results were 41.2 per cent, 40.4 per cent and 42.2 per cent, respectively. The significance of these years in which better results were obtained is lessened by the fact that they were not obtained at the end of the period studied and thus do not indicate consistent improvement in method. Instead these good years occur irregularly throughout the 8 year period. In the last 2 years the stage II results were 24.5 per cent and 28.8 per cent respectively whereas in 1935 and 1936 they were 30.8 per cent and 34.3 per cent, respectively. For stage III the relative cure rate varied from 6.7 per cent in

1938 to 22.2 per cent in 1934 with an 8 year average for 454 stage III patients treated of 17.4 per cent.

We have not attempted to draw much significance from the fact that some years gave relatively high or low cure rates for individual stages for two other reasons first, the number of patients in each stage per year is not large enough to be statistically significant second, in compiling these statistics it was necessary to reclassify into League of Nations stages I-IV the old Memorial Hospital classification of early, borderline, and advanced. Since the two types of classifications varied somewhat when compared the reclassification had to be made from descriptions on the pa-

tients charts of the extent of disease. In most cases these descriptions were adequate to permit accurate reclassification. Obviously however any such method of classification not made at the time of initial examination of the patient would tend to introduce some error into the breakdown of cases and statistics for individual stages. These objections cannot be raised against the figures in Table IV.

Most obvious in the study of these statistics is the 'plateau tendency' of the overall cure rate in Table IV. No more patients were being saved in 1941 than in 1934. Although differential study within this series had established relative superiority of 'divided dose technique' of external roentgen therapy over

massive dose technique. It became apparent that radiotherapy in cancer of the cervix had reached a maximum level of efficiency beyond which it was not advancing. In 1943 in search of improved methods of irradiation technique, a comparative study of the use of vaginal cone roentgen therapy and parametrial radon needles was begun. A preliminary report of this study was made by Taylor and Twombly in 1946. In 1945 radical hysterectomy was instituted for the treatment of selected early cases of cancer of the cervix uteri by Taylor

DISCUSSION

It has been the purpose of this paper to present the 5 year end results in 1,072 patients with cancer of the cervix seen at Memorial Hospital in the period 1934-1941 inclusive. The 5 year overall cure rate for the 1,037 patients treated by irradiation was 28.6 per cent.

The conclusion to be drawn from these studies is that there appears to be little consistent amelioration in results of the management of carcinoma of the cervix during the years studied. A perusal of reports concerning the results of irradiation therapy for carcinoma of the cervix carried out in widely scattered

centers leads to a similar impression. It therefore follows that the question must be raised as to whether or not the exclusively radiotherapeutic management of cervix carcinoma should continue to be pursued without some form of combination with surgical attack. The continued repetition in standard texts even of recent date that radical hysterectomy for cervix carcinoma is accompanied by a high mortality rate has been a strong influence in discouraging surgical attempts in this field. However, Meigs has shown that modern surgical effort in an appreciable series of selected patients should not entail significant mortality and therefore the argument of mortality does not now have the force which it did two decades or more in the past.

The problem is not one of irradiation therapy versus surgery. It is what can be done to increase progressively the incidence of cure in carcinoma of the cervix uteri?

ANGIOCARDIOGRAPHY

ANGIOCARDIOGRAPHY is the roentgenographic examination of the heart and great vessels following the intra venous injection of radio-opaque material. The first extensive use of the procedure was reported in infants by Castellanos, Garcia and Pereira, and in adults by Robb and Steinberg. It has been applied by the present writer and his associates in nearly 1500 cases comprising well over 2000 injections without any serious untoward results. Reactions to the procedure ordinarily are mild and have completely subsided in a few minutes. Rarely a transient, shock like state occurs. To minimize the frequency of this occurrence patients are carefully screened to exclude those with definite allergic tendencies and those suffering from any condition in which a rapid drop in blood pressure might not be tolerated. Severe liver or kidney damage are also contraindications. Further more individual sensitivity to the radio-opaque material is tested by the preliminary injection of a small amount.

Successful angiocardiology depends upon a well integrated team of workers. The radio-opaque material 40 to 50 cubic centimeters of 70 per cent diodrast in adults and amounts in proportion to body weight in children must be injected as rapidly as possible. For the roentgen procedure the author currently uses an arrangement which permits exposures to be made as fast as two per second. In other cases an exposure is made at every heart beat in preset phases of the cardiac cycle. He also employs motion picture photography of the fluoroscopic screen. On the other hand Temple, Steinberg and Dotter make successive photographs of the fluoroscopic screen on 70 millimeter film.

The major value of angiocardiology to the clinician resides in the delineation of the anatomy of the heart and great vessels. When the injection is successful there are visualized successively the superior vena cava, the right auricle, the right ventricle, pulmonary artery and its branches, the pulmonary veins, left auricle, left ventricle, the aorta and the branches of this vessel arising from the arch. In many children and in the occasional adult one or more of the coronary arteries have been seen. Mediastinal tumor therefore is usually easily differentiated from aneurysm since the latter fills with the opaque material along with its vessel of origin. An aneurysm which is largely filled with clot will not become opaque but the diagnosis of an aneurysm may be suggested by evidence of disease in other segments of the aorta.

The alteration in the pulmonary vascular pattern in various thoracic diseases was described by Robb and Steinberg. They refer to pressure on and displacement of the hilar

vessels by enlarged glands. They observed these changes both in primary and secondary tumors of the mediastinum as well as in tuberculosis. In pulmonary tuberculosis they describe changes in the pulmonary circulation which fall into three main types. These are diminished vascularity resulting from the narrowing and obliteration of blood vessels in exudative tuberculosis and from fibrosis in the productive type; gross displacement of the intrathoracic cardiovascular structures by extensive pulmonary fibrosis and displacement and stenosis of the pulmonary artery by tuberculous adenitis. In tuberculous fibrosis emphysema, chronic pulmonary suppuration and pulmonary cyst or neoplasm there is a decrease in the vascularity of the involved regions while in other portions there appears to be an increase in size and number of blood vessels.

Our own interest has been chiefly in lung cancer. Here we have found that an infiltrative tumor distorts, compresses and occludes the vessels in the area of involvement. When the tumor is located near to a large branch of the pulmonary artery this branch is likely to be partially or completely occluded. In the presence of a circumscribed tumor which is not invasive even though malignant the vessels are displaced and compressed but are not ordinarily occluded. Angiocardiography may be of diagnostic value therefore when bronchial neoplasm is suspected but is not proven even by bronchoscopy. Enlarged mediastinal nodes may be indicated by pressure on the large vessels but neoplastic infiltration cannot be assumed unless there is distinct irregularity in outline. The point of obstruction in mediastinitis and in certain instances of restrictive pericarditis also can be visualized as well as the collateral circulation.

Recent advances in the surgery of congenital abnormalities in the cardiovascular system

have pointed up the usefulness of angiocardiography. Thus the site and extent of coarctation of the aorta can be shown as well as the presence of an associated aneurysm. We have been impressed with the frequency of what we have called atypical coarctation in which the aorta does not show the usual uniform and progressive diminution in size but is characterized by constricted segments alternating with dilated areas. Presumably these are variations of coarctation but the constriction is not of sufficient degree to disturb the dynamics of the circulation. On the other hand, an associated constriction of a major vessel such as the subclavian artery which is frequently demonstrated on the angiocardiogram, may be clinically manifest.

An alteration in the outline of the proximal descending aorta is found regularly in the presence of ductus arteriosus but this does not necessarily indicate patency. In most cases, according to the observation of A. S. W. Touroff made at operation, this probably represents a local fusiform dilatation of the aorta but in some cases it might be a traction aneurysm or the outline of the infundibulum of the ductus. When a large shunt is present, the pulmonary artery is revascularized. In the tetralogy of Fallot the anatomical features of pulmonic stenosis and right ventricular hypertrophy are shown and in addition, the shunting of blood from the right ventricle into the overriding aorta and into the left ventricle. The size of the pulmonary artery can ordinarily be made out but failure to visualize this vessel does not necessarily indicate pulmonary atresia. The position of the aortic arch and its branches also is useful preoperative information. In the Eisenmenger complex, there is a similar appearance but without pulmonic stenosis and with a dilated pulmonary artery. In this condition there is less of a venous arterial shunt so that although the aorta is

visualized simultaneously with the pulmonary artery, it is not as dense as in the tetralogy

We need not here detail the findings in other congenital lesions. Suffice it to say that the combination of an accurate history, careful physical examination, electrocardiography, and when necessary the application of such special techniques as cardiac catheterization, angiocardiology, and microplethysmography permit a complete anatomic and physiologic diagnosis in most cases. The same combination of procedures has added immeasurably to our understanding of the altered cardiac dynamics found in normal subjects during exercise and in those with right ventricular strain due to mitral disease and pulmonary insufficiency. We may confidently anticipate that the continued integrated use of these methods will inevitably increase our understanding of and diagnostic acumen in cardiovascular disease.

MARCY L. SUSSMAN

IS THERE AN ADEQUATE THERAPY FOR REGIONAL ENTERITIS?

ALTHOUGH surgery at present offers the best opportunity for palliation and control of regional enteritis, an extensive experience with this disease at the Beth Israel Hospital in Boston indicates that the end results of any and all treatment leave much to be desired. Many of the questions raised when the disease first became generally familiar are still unanswered. For instance, we do not know whether the disease is an infection, a nutritional deficiency disease or a psychosomatic disorder. As surgeons we stand in regard to this disease in a worse position than we do with ulcerative colitis because colectomy can provide a final and definitive cure for ulcerative colitis while excision of the involved bowel in regional enteritis frequently does not

It has recently been stated that if all inflamed loops of small bowel are not removed, recurrence or inadequate control of the disease is the result. But the fact is that recurrence may result even if all the inflamed loops are removed.

The frequent occurrence of unsatisfactory end results following surgery naturally brings up the matter of nonsurgical treatment. What is the medical treatment of regional enteritis and what does it have to offer? The medical treatment of regional enteritis aims at improving and maintaining nutrition, correcting anemia and relieving pain and diarrhea. A high vitamin, high protein, high carbohydrate, low residue diet with liver, iron, and calcium supplements and the judicious use of sedatives and antispasmodics and of chemotherapy are the chief therapeutic measures available. Finally, since many patients with this disease have psychosomatic difficulties, psychotherapy is also thought by some to be helpful.

How effective is medical management? The earliest form of the disease is occasionally encountered as an unexpected finding in patients operated on for right lower quadrant pain. Some of these patients have recovered without further therapy of any kind. Some have not. Some of those who have had medical care have become well sooner or later and have avoided surgery. It is impossible to tell whether arrest of the disease was achieved because of the medical therapy given, but all are agreed that spontaneous arrest does occur. This being so, no patient should be subjected to surgery simply because he is known to have the disease. The symptoms must be disabling and must have failed to yield to the best medical treatment, because surgery is certainly not a completely reliable therapy whatever the stage of the disease with which one is dealing. It is pertinent to inquire whether the best medical treatment as here described can still be im-

proved? Possibly. The intestinal antibiotics have not been sufficiently exploited. Massive local and parenteral chemotherapy is sometimes accompanied by at least temporary improvement, so striking as to be hardly coincidental.

The need for surgery in a substantial percentage of patients will be unavoidable because of the intensity of suffering or the speed of deterioration or both. Whether we are adherents of one or another form of therapy abscess, fistula, organic stricture or hemorrhage will compel surgery. But what has surgery to offer patients without these complications? The picture is not too bright despite many optimistic reports by surgeons. It is stated in a paper published in 1945 that resection in chronic terminal ileitis was satisfactory in 35 of 44 cases followed for over one year. It is important to point out that a satisfactory result for one year is no more a test of cure of regional ileitis than it is of cancer of the breast. We have recently had a patient who was well for fifteen years after a resection for regional enteritis and who then developed extensive recurrence which required a second resection. We could cite many similar cases of recurrence years after what appeared to be an adequate resection. Everyone knows however that removal of all the visibly involved bowel is not equivalent to complete eradication of all diseased tissue because the involved lymph gland area is far more extensive than the involved bowel. One might ask whether it is desirable or possible to remove all lymph nodes? That it is desirable is questionable, that it is possible is almost certainly not the case because even the nodes which are not palpable may also be involved. Recurrence is not uncommon in the glands as well as in the bowel considerably proximal or distal to an anastomosis performed in an area free of disease. So it is not surprising that some authorities now conclude that resec-

tion is best avoided and that a defunctioning ileocolostomy is preferable. But is great confidence justified in a defunctioning ileocolostomy? A review of what has happened to the patients who have had this procedure fails to support the optimistic view of its proponents. We have seen patients in whom ileocolostomy and exclusion failed completely to protect against further spread of the disease, which in some cases ultimately involved most of the small intestine. Nor did subsequent extensive intestinal resection with a new anastomosis between normal loops of bowel succeed in restoring some of these patients to good health. Regional enteritis may not only progress proximally to involve large areas of the small intestine but may also advance distalward and produce a lesion which may be indistinguishable from ulcerative colitis.

From a review of our experience we have concluded (1) that no patient should be given definite assurance that he will be cured by surgery (2) in about half the patients requiring surgery a defunctioning ileocolostomy or resection will provide sufficient relief without the need for a subsequent operation. In the other half reoperation may sooner or later be required, but if a second operation is required, the likelihood of benefit from it is less than from the first, whatever type of operation is performed. The choice of procedure is by no means established. A working rule for the present might be (1) a defunctioning ileocolostomy for the uncomplicated and (2) primary or two stage resection for the complicated case.

We are dealing with an inflammation in which no specific bacterial flora can be incriminated and yet the disease has all the earmarks of an infection. Finally frequent failures by both surgical and medical treatment emphasize the need for a more intensive study of the pathogenesis of this disease.

"AND SO TO BED

ESTHER H VINCENT Evanston Illinois

IN the days when Oliver Cromwell was lording it over England in true Puritanical style, there came down to London from his native Huntingdonshire, a young tailor by the name of John Pepys. As far back as the reign of Edward I there had been Pepyses in the fen-country. Theirs was an orderly and administrative clan slowly rising from the yeoman farmer class to that of gentry and, since 1563, even sporting a coat of arms. In the early years, when monasteries and other church communities had blossomed like roses among the green hedges of that rich level country the Pepys men had flourished as business agents for the church dignitaries.

John, the tailor, was a younger son and so quite naturally went into trade. In London he married fifteen year old Margaret Knight, the pretty but stately sister of a White chapel butcher and wash maid to my Lady Vere. This was regarded as a mésalliance even by the children who were wont to refer to their maternal ancestry with a certain disparagement. However the young couple settled down to family life in a house in Salisbury Court Fleet St. hard by St. Bride's and almost opposite the present offices of *Punch*.

In spite of a marked lack of cordiality on the part of the exclusive Merchant Tailors Guild, pro-

vincial Mr. Pepys prospered and did so well that he was able to educate his children properly. Young Sam, born in 1633, was the fifth child and the second son of a large family, all of whom he survived. Educated in Huntingdon and at St. Paul's, London, he went up to Cambridge at barely eighteen. He entered Trinity Hall in 1650 but migrated

shortly via a scholarship to Magdalene College where he took his degree in 1653. Little is known of his undergraduate career but it is recorded that he wrote a romance, *Love is a Cheat* which he later destroyed, and that, along with another lad, he received a public scolding for having been scandalously overseen in drink. It is certain however that he made good use of his study hours for in later life, he found himself possessed of a fuller store of learning than that of most of his associates.

Samuel's great aunt Paulina had married Sir Sydney Montague a noble roundhead and became the mother of Sir Edward Montague friend of Cromwell and colonel in his army. Later Sir Edward served as Vice Admiral of

the Fleet under Blake, became a full Admiral, and in spite of his puritanical past, was created first Earl of Sandwich by Charles II. Until his death in action at sea Sir Edward was Samuel Pepys's great friend and patron. It was through the efforts of this titled relative that Pepys secured public employment. When he first took office he

Samuel Pepys
1633-1703

After the portrait by John Clarke

From the Archibald Church Library Northwestern University Medical School.

was so ignorant of business that he did not even know the multiplication table, but he soon mastered all mechanical details by working overtime. The year 1660 saw him appointed Clerk of Acts in the Navy Office, and 1673 witnessed his elevation to Secretary of Naval Affairs. True to the tradition of his ancestors, he was an excellent public servant, shrewd, diligent and laborious. The only check to the flowing tide of his public life was during the fanatical excitement of the Popish Plot, when he was sent to the Tower on a trumped up charge of treason.

His scholarship and general culture were such that he achieved fellowship in the Royal Society and was its president for two years. At various times he was Governor of Christ's Hospital, Master of Trinity House, and Master of the Clothworkers' Company. He represented Harwich in Parliament. His chief literary effort, other than the famous *Diary*, was the *Memoirs of the Royal Navy* published in 1660. An inveterate collector he surrounded himself with books, manuscripts, prints, ballads, and illustrious friends.

This great and good servant of the King kept a shorthand diary for almost ten years of his gayly respectable life, an intimate, gossipy personal chronicle that has delighted a gasping world. Not only does it reveal the life of a bright, young man-about town, an important public official during the Restoration, but it discloses with psycho-analytic frankness the secret activities of personality that most men hesitate to acknowledge even to themselves. There is nothing like it in any other language! His weakness for drink, fine clothes, playhouses and ladies, his marital relations, his back-stairs gossiping and wire-pulling, his good resolutions and his back-slidings, all are set down with candid-camera clarity. To read the *Diary* gives one a series of little, pleasurable shocks, as well as an amusing picture of the racy London of his day.

Robert Louis Stevenson regards Pepys as an eternal child, who preserved to middle life the gusty emotional immaturity of adolescence. Sweetly sentimental about himself, he sought with boyish anticipation all the joyous, worldly show. He must always be doing something agreeable and always be doing it with someone. He "knew not how to eat alone." A sterling humanist, he came very near to being an artist. Gleefully following the footsteps of the contemporary Mrs. Grundy his morals were decent enough for his times. Respectability meant much to him, and he was wont to repent only when found out. He could not be bribed, but was not so squeamish as to receive a present after. All is set down with happy ear-

nestness and with completely unconscious humor.

In December 1655, at St. Margaret's, Westminster Samuel married fourteen year old Elizabeth Marchant, daughter of a Huguenot refugee and an Irish woman. Elizabeth was pretty and very good company when she is well. She had a bright, clever little face, with a long upper lip, a full bosom, and a stylish forehead-curl. She chattered away in both English and French, and set out to learn arithmetic, music and globes from Sam. She was a good wife with a spirit of her own, although she had much to put up with. Sam was infernally jealous, yet saw no reason for loyalty on his own part. The Deb Willet episode of November 1668 turned Elizabeth into an outraged Juno, and the *Diary's* wrong dating and expressions of 'phrenzy' show Sam's mental reactions.

Elizabeth a memorial bust, erected by her husband in St. Olave's, Hart St., shows that she probably had adenoids, and it is known that she suffered from dysmenorrhea for many years. We know also that she had toothache and canker, the latter probably due to wax, since syringing cured it. In 1663 she had a perineal abscess which ended in a fistula.

On November 16 1663, "Mr. Hollyard came, and he and I about our great work to look upon my wife's malady which he did, and it seems her great conflux of humours heretofore that did me to swell there did in breaking leave a hollow which has since gone in further and further till it is now three inches deep, but as God will have it did not run into the bodyward, but keeping to the outside of the skin and so he will be forced to cut open all along, and which my heart will not serve me to see done, and yet she will not have no one else to see it done, no not even her mayde, and so I must do it poor wretch for her.

Next morn Mr. Hollyard on second thoughts "believes a fomentation will do as well, and what her mayde will be able to do as well without knowing what it is for but only that it is for the pain. Mr. Hollyard received three pounds "for his work upon my wife, but whether it is cured or not I cannot say but he says it will never come to anything, but it may ooze now and again.

An ischio-rectal abscess is the probable diagnosis, although considering her husband's rampant habits, she may have acquired an acute inflammation of Bartholin's glands.

Later she had abscesses in the cheek which "by God's mercy burst into the mouth, thus not spoiling her face. This plus the frequent toothache may have been due to pyorrhea. Elizabeth never became pregnant, although she had a couple of false alarms.

After fifteen somewhat hectic married years, she died in 1669 when only 29. The two Pepyses had just returned from a visit to France and the Low Countries when Elizabeth fell desperately ill of a fever. Speculation as to the cause of death runs to typhoid or a septic pneumonia arising from pyorrhea.

The *Diary* abounds in medical topics—scrofula, smallpox, and plague in addition to the author's own afflictions of indigestion, colds, eye strain and urinary calculi. His life long anxiety regarding the stone began with a country hike when the 20 year old Pepys and his Cambridge friends went out to visit a famous well. The hot and thirsty Samuel drank copiously of the cold water and upon returning to his room suffered an attack of renal colic. After several painful days, the stone dropped into the bladder. Contrary to the usual sequence this stone was not voided and may have formed the nucleus of the calculus which brought him to the operating table 5 years later. His mother once voided a large stone, which she threw into the fire and later a brother developed symptoms of the same nature.

The outstanding event of Pepys's life was his operation for removal of the stone. This occurred on March 2, 1678 and ever afterward Pepys observed the day with pomp and circumstance. Most people of the seventeenth century endured surgery with little aid other than stout hearts and sluggish nervous systems, and so it was with Pepys poor wretch.

Cutting for the stone originated in India and reached Greece early enough to be mentioned in the Hippocratic Oath. The operation was first performed only on children. The child was held on the lap of one muscular assistant, while two others held its arms and legs. The surgeon put one or two fingers in the little anus and tried to push the stone down on to the perineum while another assistant made use of hypogastric pressure. The surgeon then made a transverse incision above the anus, praying to the gods that he would hit the neck of the bladder. He then attempted to push out the stone with his fingers still in the anus. If this did not work he grabbed the stone with forceps and pulled it through the perineum.

Later improvements included employment of still another assistant to sit on the patient's chest, and further resort was made to tying the patient with ropes. Pepys was probably kept quiet with yards of hemp. One can imagine the solemn arrival of the surgeon at the house with his dread army of assistants and tools. Two operations were current, that with "little apparatus" and that with grand apparatus.

Preparations consisted of placing the patient on the table with head raised and buttocks projecting beyond the end. The legs were flexed at the knees and tied with ropes in a sort of clove-hutch. Two or three assistants held the victim, and he may have been given a sedative (mandrake or a sleeping sponge) saturated with a solution of opium, hemlock or other soporific.

Operative procedure for the "little apparatus" consisted of inserting a finger into the anus, steady ing the stone or pulling it down to a bulging perineum cutting directly upon it and pressing from above or extracting with forceps. The "grand apparatus," probably the technique used on Pepys, was a modified Jacques's operation with grooved staff and scalpel, a lateral incision and division of the prostate.

Since diagnosis was still primitive and differential diagnosis doubtful the wise surgeon provided himself with a spare, an extra stone to fasten upon the patient in case his efforts were unproductive. No small stone was ever cut out, for the patient naturally waited until his fear of the stone exceeded his fear of the cutting.

As a result of this operation some men went around with unhealed wounds, and some died of hemorrhage. Others lost control of the sphincter vesicae were left with urinary fistulas, or lost their procreative power through interference with the seminal vesicles and ducts. The mortality was 15 to 20 per cent.

It is no wonder then, that Pepys kept holy the anniversary of his operation nor that he edged the story of it into every possible conversation. Nor that his interest in urinary pathology was so aroused that he voluntarily attended a lecture at Chirurgeon's Hall and visited the dissection room where a certain Dr. Scarborough discoursed to him on the manner of the disease of the stone and the cutting and all other questions that I could think of.

Pepys's stone weighed about 2 ounces and was as large as a tennis ball. It was probably a uric acid calculus or had a uric acid nucleus with ammonium urate covering. Pepys kept it for years and even had a pretty case made for it. Immediate result of the ordeal was satisfactory, but Pepys continued to suffer from renal colic all his life. He tried to ward off attacks by keeping a hare's foot in his pocket. A friend told him that the foot's lack of a joint made it inefficient. How ever

It is a strange thing how fancy works for I no sooner almost handled his foot but my belly began to be loose and to break wind and whereas I was in some pain yesterday and t. other day and in fear of more today I became very well and so continue."

When he died, an old man, his left kidney was found to be disorganized and contained seven calculi all fast linked together and weighing four ounces."

By injuring both his vasa deferentia, the operation left him sterile but not impotent. The *Diary* shows him to have been in a more or less constant state of sexual excitement. His unusual incontinence may have been due to the continual irritation of the old scar on the perineum. Freudian complexes to the contrary, some insignificant irritation may make all the difference between virtue and concupiscence.

When he crossed his legs carelessly a mild epididymitis ensued, much to his annoyance. And a sudden change from warm to cold weather would bring on severe pain—a probable reflex irritation from his kidney stones. In later life he seems to have been stricken with Bell's palsy and with something else that resembled pseudo-fleus, possibly another sort of reflex from his latent calculi. Everybody on the street witnessed his anguish and all the ladies sent in directions for enemas. The prescription that relieved him consisted of small beer.

Pepys's surgeon was Thomas Hollier lithotomist at St. Thomas's Hospital, and one time Warden of the Barber Surgeons' Company and later Master that same Holliard who was called in to see Mrs. Pepys. Hollier had a reputation as a successful stone coter having cut thirty persons in one year without a death. It was fortunate for Pepys that Hollier's instruments had not yet become septic. Attending with Hollier were Dr. James Moleyns, lithotomist at St. Bartholomew's Hospital, and also Dr. George Joyliffe, who shares claim to the discovery of the lymphatics. The Sloane collection of manuscripts contains two subscriptions written for Pepys at the time of his operation. One of them reads:

For M^r Peapys who was cut for the 1000th ye 8 March.
653 and had very great stone taken that day from him
(Signed) Dr J M Dr G Jolly

Its main constituent was lemon juice to which a little syrup of radishes was added. Evidently Mr. Pepys was expected to have a little fever but was not thought to be seriously ill, for the prescription states that the mist. alba was to be sine moscho. At that time musk was considered to be the best remedy for grave illness, and few people died without a musk viaticum.

Dr. James Moleyns was Surgeon of the Stone at both St. Bartholomew's and St. Thomas's, and the College of Physicians granted him the unusual privilege of administering drugs in surgical diseases.

He signed the first prescription alone and with his initials, like a physician. Surgeons signed their full names.

In May 1660 Pepys had gone over to Holland with the ships which were to bring Charles II back to England. There was the usual royal salute with much firing of cannon. Holding my head too much over the gun, I had almost spoiled my right eye." Two years later at Portsmouth, Pepys "was much troubled in my eyes, by reason of the healths I have this day been forced to drink, and on returning to London he was let blood, about six ounces by Dr. Hollier who received five shillings for his pains.

By 1664 Pepys was having eye pain after long reading or writing and made use of a globe of glass and a frame of oyled paper" to lessen glare. His experience was that of many another man in his thirties, when the strain of focussing, dependent upon some refractive error, has begun to send out SOS calls.

No mention of eye distress occurs in 1665, the year of the Great Plague and also a year of great naval activity. In May 1666 his right eye was sore and full of humour" a unilateral conjunctivitis, blamed upon "my late change of brewer. On December 24th he bought a pair of green spectacles. During 1667 only four entries suggest eye discomfort, but on November 4th he sought Tillington, the spectacle maker. In 1668 he consulted Turberville.

Turberville (D'Aubigny D'Urberville) had lately come up to London from Salisbury where he practiced as an oculist. The court physicians looked upon him as a country quack and yet he was able to cure Queen Anne of sore eyes when she was a child. Oculists of that day founded their art on superstition and folk-lore and knew little more than the corner drug-store clerk of today. They could make some simple but bunglesome refractions, and what cures they made were induced by chance. Their mercurial eye-washes may have helped heal venereal affections of the eye. And they had some knowledge of spectacles, such as they were, for both convex and concave lenses had long been discovered. But astigmatism was not recognized until 1827 and of simple accommodation men like Turberville knew nothing. Yet Turberville's tomb in Salisbury Cathedral bears this inscription,

"Near this place lies Interred the most expert and successful oculist that ever was and perhaps ever will be.

It is not apparent that Turberville did much for Pepys. No pre-nineteenth century oculist could have done much. Sir D. Arcy Power considers

Pepys's defect as hypermetropia with slight astigmatism. R. R. James thinks that much of the trouble was caused by muscle imbalance, possibly insufficiency of convergence. The spectacle maker would hardly have dissuaded him from the old spectacles, the higher plus spheres if a large hypermetropic error had been present, and Pepys himself admits that for a short reading period he could see as well as ever. That unocular vision in a tube relieved him is in favor of his defect being concerned with binocular vision.

Poor Pepys's inability to get proper spectacles brought him to the sad conclusion that he was going blind. His entry for May 31 1669 reads,

"And thus ends all doubt I shall ever be able to do with my own eyes in the keeping of my journal I being not able to do it any longer having done it now so long as to undo my eyes almost every time that I take a pen in my hand. And therefore whatever comes of it must forbear."

Of course, he did not lose his sight and as late as 1702 he was writing letters with his own hand though he preferred dictating them. The increasing sclerosis of the lenses prevented his readjusting their curves, and neutralizing the insufficiency and asymmetry of his corneal curvature. When he automatically gave up trying to do the impossible he got relief. He needed a pair of compound lenses—spheres for his long sight and cylinders for his coincident astigmatism.

Pepys's minor ailments included frequent indigestion and colds. Once he had tonsillitis from sitting sweating in the playhouse with the wind blowing through the windows on my head. And once he had a boil under my chin which troubled me cruelly.

The *Diary* records his interest in the King's Evil, in smallpox, and in the plague, the ravages of which he witnessed. As guest of chyrurgeon

Pierce he once witnessed a dissection of the genitourinary system. He also saw an early mastectomy. He was an intelligent observer of the first successful blood transfusion in dogs.

Sharing the current belief in tobacco as a plague preventive he tried out a 'chaw' one day and soon lost his sense of apprehension probably via the emesis that followed his unaccustomed use of the weed.

On the accession of William and Mary Pepys retired to his books and his music, to his correspondence with Sir Isaac Newton Dryden and other sons of fame. And so to the grave in 1703 at the ripe age of seventy-one!

The exact necropsy findings are unknown but there was gross pathological evidence of arteriosclerosis. The calyces of the left kidney contained a nest of seven stones. Note is made of the scar on the perineum. There is a probability that he had prostatic hypertrophy resulting in urgency and frequency of miction rather than ordinary incontinence.

The importance of the postmortem lies in the fact that, for the first time an autopsy had been done on a colorful interesting character in English life a circumstance that proved to be a valuable asset to the medical scientists of the period.

REVIEWS OF NEW BOOKS

IN the second edition of *Physical Medicine in General Practice*, the author has included the advances which were made in physical medicine during the last World War and the results of the work done by the National Foundation for Infantile Paralysis, as well as some of the newer subjects such as the combination of penicillin and fever therapy in syphilis and early ambulation in medical and surgical conditions. In the first fifteen chapters the physics and the physiological response of the tissues to the various modalities employed in physical medicine are discussed. The use of the modalities is described in sufficient detail so that a general practitioner can write an adequate prescription to enable the physical therapist to carry out accurate treatment. The chapters which deal with hydrotherapy and short wave diathermy are particularly well presented.

In the chapter on Medical Rehabilitation the author touches on all aspects of physical medicine and rehabilitation in the various types of conditions. This includes educational and vocational rehabilitation.

The last nine chapters of the book present diseases of the various body systems and the physical medicine measures which would be used as an adjunct to their treatment. L. J. CONNORS, JR.

THE editors of *Principles of Occupational Therapy*, Helen S. Willard and Clare S. Spackman in collaboration with nineteen other authors, give a clear and complete description of the subject from the present day standpoint. The book is divided into two main sections. The first section deals with the basic concepts in occupational therapy, outlining its history, scope, and aims and including a chapter on organization of an occupational therapy department. The second section discusses the applied principles in various types of hospitals and, too, in dealing with various types of disease and injury. The various activities and the way in which they may be used in the treatment of specific illnesses or injuries are well presented. In addition many of the activities described may be useful in the care of the patient for recreation even though they cannot be classed as treatment. The chapter on occupational therapy for patients with physical injuries is particularly well done. The association between occupational therapy and physical therapy is also brought out in this chap-

ter. The chapter on occupational therapy for patients with mental disease is especially good and it would appear that in this branch of medicine occupational therapy has its greatest usefulness. The educational aims of occupational therapy as presented are an excellent goal and would contribute considerably to the efficiency of occupational therapy in the treatment of patients. The final chapters of the book outline the organization and activities of occupational therapy in Army, Navy and Veterans' hospitals.

Particularly individuals having to do with the care of industrial or institutional cases would find this book of value. L. J. CONNORS, JR.

THE third edition of *Recent Advances in Sex and Reproductive Physiology* by J. M. Robson represents a revision of the 1940 edition and has a moderate amount of newly added material. It is concerned with sex and reproductive physiology of the female only. Sixty-five illustrations are listed but a good share of these are diagrams, tables, and graphs.

According to the foreword the book was written to answer the questions of perplexed physicians. The emphasis, however, is placed on the presentation of experimental animal data. For example, in the section on cyclic changes in the endometrium, the first half of the discussion is concerned with the mouse, rat, rabbit and bitch. The second half is devoted to primates, but man comes off a poor second in that most of the attention is devoted to the monkey. Some of the scanty human data could better have been omitted. Specifically a full page is devoted to the outmoded and erroneous descriptions by Saw (1925) of the cyclic changes in the endometrium. Schroeder's description is included but the significant works of Robert Meyer and Emil Novak on this subject are ignored. In fact, the innocent reader is left with the impression that this particular subject is one that is obscure and subject to great controversy.

In general the author's citations are representative of data obtained from experimental animals although the rabbit is obviously Dr. Robson's favorite experimental animal. He has however made a good effort to evaluate critically the animal data. For this reason the book will be of value to some laboratory workers. Its reference value is limited, however, by the incompleteness of its survey of the literature.

The reviewer doubts that the book would be of great value to the perplexed clinician.

R. R. GREENE

"RECENT ADVANCES IN SEX AND REPRODUCTIVE PHYSIOLOGY BY J. M. ROBSON, M.D., D.Sc. (Leeds) F.R.S.E. 3rd ed. Philadelphia and Toronto: The Blakiston Co., 1947

PHYSICAL MEDICINE IN GENERAL PRACTICE. By William Bierman, M.D. With a chapter on Medical Rehabilitation by Dr. Sidney Licht, M.D. 2nd ed. New York and London: Paul B. Hoeber Inc. 1947.

PRINCIPLES OF OCCUPATIONAL THERAPY. Edited by Helen S. Willard, B.A., O.T.R. and Clare S. Spackman, B.S., M.S. in Ed. O.T.R. Philadelphia, London, Montreal: J. B. Lippincott Co. 1947.

THE high caliber of the first four editions is maintained in the fifth edition of *A Textbook of Pathology, an Introduction to Medicine* by Dr William Boyd.

Again Dr Boyd has saved time for the cursory reader by outlining in his preface the new material which has been added to the content. This material has been well selected. As in previous editions emphasis is laid upon photomicrography which is adequate and illustrates the individual lesions satisfactorily. The photographs of gross specimens are well distributed. The chapter on diseases of the central nervous system and that of bones is especially well organized.

The reviewer sees one minor criticism that being an outmoded bibliography.

It would be advantageous if Professor Boyd could in his next edition add chapters on diseases of the skin, the eye and of the ear, nose and throat. Additional space might be devoted to the effects of heat and cold of physical trauma including blast injury and to the morphologic changes of radiation. These would enhance the value of this standard text.

M C WICKLOCK.

AN exhaustive treatise on cystitis and diseases of the urinary bladder has been written by Luis Cisneros Delatte.¹ The author bemoaned the paucity in the literature of material on this subject and therefore conceived this work to fill in the skipped spots. He draws liberally upon what others have done and written before him from his own experience he supplies what was lacking to give a complete well rounded study of the inflamed bladder.

The book is divided into two parts. The first treats of general concepts regarding cystitis and cystopathies. The normal bladder mucosa is described and the departures from this normal mucosa are compared in the various bladder diseases. A chapter on etiology includes a study of the many bacteria which may cause cystitis their virulence, and the peculiar bladder reaction to the particular infection. Cystoscopic exploration and methods of obtaining biopsy material as well as general principles of treatment are given. The new chemotherapeutic and anabolic substances receive special emphasis. The various recognized classifications of cystitis are reviewed. These the author believes are inadequate. He proposes a classification which appears all inclusive and divides cystitis into primary and secondary. The former discusses bacterial, parasitic, viral, chemical, physical, and toxic. The latter takes up subjects as neoplasms, stones, malformations, trauma, fistulas and the like.

Cystopathies make up the third section of the classification. Among others such topics as cystitis, leucoplakia, allergies, amyloidosis and malacoplakia are considered.

A TEXTBOOK OF PATHOLOGY, AN INTRODUCTION TO MEDICINE. By William Boyd, M.D. Dipl. Psych. M.R.C.P. Edin. F.R.C.P. Lond., J.L.D. Sask. M.D. Osk. F.R.S.C. 5th ed. Philadelphia, Lea & Febiger, 1947.

CYSTITIS Y CISTOPATIAS. By Luis Cisneros Delatte. Madrid Editorial Pax Montalvo, 1947.

The second part of the book is devoted to specific forms of bladder diseases. Tuberculosis, gonorrhea, actinomycosis, bilharzia, and lymphogranuloma each have complete chapter discussions. Trigonitis is given emphasis proportionate to the importance of this disorder and alone makes the volume a valued possession.

The book has 176 illustrations, 82 of which are in color and depict the pathologic process in amazingly sharp detail. The volume is a credit not only to the Spanish medical literature but represents a positive advance in worldwide urologic conceptions.

STEPHEN A. ZIDMAN

THE third edition of the monograph on *Hernia* by Watson² deserves a place as a standard reference on the subject. All types of hernia are described with their chief symptoms, mechanism and recommended methods of treatment. Many illustrations are used to explain the text. The author is justifiably critical of many operative procedures and advised those methods which have been most widely accepted. He is quite opposed for example, to fascial suture repairs to which he objects as more traumatic than a carefully performed repair by means of fine suture material with or without fascial patch or cutis grafts.

There are many changes from the second edition. The author now advises silk or cotton suture instead of absorbable suture material. A new section on the repair of Cooper's ligament has been added. Early ambulation has been substituted generally for prolonged bed rest. Chapters have been added on the truss treatment of berna and industrial berna.

It seems unfortunate that a reference work otherwise so acceptable should have devoted so much space (68 pages) to the injection treatment of berna. So far as the reviewer is concerned injection treatment should have been mentioned only to be condemned. The author's statement that in hernias previously treated by injections the dissection is a little difficult seems a gross understatement.

THOMAS C. DOUGLASS.

A comprehensive report on the cytological changes in the epithelial structure of the female generative tract is presented in *The Epithelia of Woman's Reproductive Organs*³ by Drs. George N. Papanicolaou, Herbert F. Traut, and Andrew A. Marchetti. This study represents a co-operative effort by a group of workers with biologic, physiologic, and gynecologic interests and contributes to an understanding of functional characteristics of the female generative tract. The material for this study was obtained from the Woman's Clinic of the New York Hospital and

HERNIA. ANATOMY, ETIOLOGY, SYMPTOMS, DIAGNOSIS, DIFFERENTIAL DIAGNOSIS, PROGNOSIS AND TREATMENT. By Leigh F. Watson, M.D. F.R.C.S. 3rd ed. St. Louis, C. V. Mosby Co. 1948.

THE EPITHELIA OF WOMAN'S REPRODUCTIVE ORGANS. By George N. Papanicolaou, M.D., Herbert F. Traut, M.D. and Andrew A. Marchetti, M.D. New York. The Commonwealth Fund, 1948.

the monograph is based on a ten year study conducted by the Departments of Anatomy and Obstetrics and Gynecology of Cornell University.

The changes in the ovary are accurately described starting with the developing follicle and continuing through ovulation and corpus luteum development. The changes in the epithelia of the tubes, uterine mucosa, endocervical glands, portio vaginalis of the cervix and vagina are then correlated with the cyclic change which occurred in the ovary. The descriptive text frequently refers the reader to the section of the book containing the photomicrographs and the beautiful drawings of Hashime Murayama. These illustrations help to tell an important part of the story and for any student of the cytology of the female genital tract these drawings will be a great help in recognizing and identifying the cytologic changes which occur. A large colored chart at the close of the book serves to correlate all of the cytologic changes which occur in the various sections of the tract during each phase of the menstrual cycle. These authors have made a significant contribution which is well presented.

FRANCIS M. TROSBELL.

MANY new therapeutic agents in the treatment of diseases of the ear have been studied during the war period and are just now coming to the notice of the otologists. These have all been added to the second edition of Nelson's *Loose Leaf Medicine of the Ear* and undoubtedly will prove useful when applied to the civilian population. The chapter on otologic aspects of aviation should be helpful to otologists and aviation companies as well.

The book has not suffered from the delay caused by the war, in fact the delay has been useful in that it allowed time for the latest investigations to appear in print.

The book is printed on good stock and is profusely illustrated. It should prove a quick and ready reference for the latest work in medicine of the ear.

JOHN F. DILLON.

AN excellent condensation of the periodical literature for the year 1947 is presented in *The 1947 Year Book of Obstetrics and Gynecology* edited by J. P. Greenhill. The abstracts have been prepared with commendable clarity and faithfully portray the gist of the original work. The several illustrations are well chosen and well reproduced.

Dr. Greenhill's comments while presenting his personal views, with which there will naturally be occasional disagreement, are written in a pleasant conversational style.

During the many years of their publication the year books have almost become institutions in American medicine. They serve their purpose admirably in that they supply readable accurate summaries

RECEIVED PAGE IN THE LOOSE LEAF MEDICINE OF THE EAR, Edited by Edmund Prince Fowler, J. M.D. Med. Sc.D. New York and Edinburgh: Thomas Nelson & Sons, 947

1947 YEAR BOOK OBSTETRICS AND GYNECOLOGY Edited by J. P. Greenhill, M.D. Chicago: Year Book Publishers, Inc., 947

not only to the physician who is too busy to read all of the current journals but also to anyone who wants a comprehensive review of the work in any special field. This book is a worthy addition to its many predecessors.

JOHN W. HERRICK.

A NEW surgical outline which will appear in a series of volumes is being published under the title *British Surgical Practice*. The two editors-in-chief, Sir Ernest Rock Carling and J. Paterson Ross have selected specialists in many fields and have given them a free hand in discussing the details concerning a host of problems confronting the average surgeon. cursory examination of the first volume, without careful study of the introduction, immediately suggests unfavorable criticisms which are not tenable after one has studied the introduction. The editors-in-chief state at the outset that the series of volumes is prepared for the many physicians who lack easy access to libraries or medical centers. The work is directed primarily to these surgeons and is not intended to expound the minute details of highly specialized techniques. The outline is established, nevertheless, to show the average surgeon what might be accomplished by a highly trained expert in a certain field, working under the best possible conditions. The editors hope that the series will serve as a guide to those to whom is entrusted the surgical care of any type of patient. They admit freely that the specialist will not find the work of great advantage in his own case, but they would suggest that there are indeed problems which might be profitable for the specialist to peruse. The editors hasten to caution medical students that the volumes are not intended especially for them, but they point to the all too rare quality of simplicity which has been achieved primarily by having only masters in knowledge and in expository skill to write the outlines in each field.

One refreshing feature of this volume which we hope will be evident also in the forthcoming volumes is the exclusion of obsolete procedures even though they may have become famous because of the relative renown of some of the older masters. The editors-in-chief accept full responsibility for the subject material, but they caution the reader "bearing chosen our man, we should allow him to express his preferences without undue interference."

The first volume takes the reader from Abdominal Emergencies to "Autonomic Nervous System." The general setup of the volume is unusual in that the alphabetical arrangement is the primary means of listing subjects. This affords immediate and convenient access to descriptions of clinical phenomena and syndromes which might be puzzling the surgeon. The matter is thoroughly outlined in a consistent fashion. There is a profusion of excellent illustrations and a decided advantage is the marginal list

BRITISH SURGICAL PRACTICE. Under the general editorship of Sir Ernest Rock Carling, F.R.C.S. F.R.C.P. and J. Paterson Ross, M.S., F.R.C.S. Vol. London: Butterworth & Co., Ltd. St. Louis: The C. V. Mosby Co., 947

or label index which renders the work simplicity itself.

The chapter on abdominal emergencies is well done and treats of all of the important features without going into tiresome detail about any. The list of references is somewhat short but by referring to the articles mentioned, the reader will find further bibliography which will lead the way to rather complete discussion.

The chapter on abdominal incisions presents most of the conventional information with a few additions which are perhaps innovations to the American surgeon.

The chapter on abscesses appears notably lacking in a thorough discussion of modern chemotherapeutic adjuncts and antibiotics. Closer examination of this part of the chapter suggests that that is exactly the intention of the author. His major premise is that the treatment of abscesses is always surgical drainage, and it is implied that the surgeon will do well to keep that thought uppermost rather than to lean on therapeutic aids at an improper time. This is just one example of a delightful British manner of writing which displays itself throughout the volume. The habit of understatement has a tendency to emphasize facts which the careful surgeon will have in mind and the style throughout is pleasant and makes for easy reading.

The chapter on actinomycosis is especially good and is accompanied by some excellent illustrations. The portion on treatment is most up-to-date and seems to be well in accord with the experience in various centers throughout the United States.

Considerable attention is given to adhesions and the author advocates a rather middle course in their treatment. The outline is followed in strictest detail here and protects the author from giving too much space to his own personal conclusions in regard to the importance of adhesions.

The adrenal glands come in for discussion affording a rather quick and easy outline for the surgeon who throughout his entire career probably will not encounter more than one or two cases in which he must operate on these organs. The illustrations here are excellent and the implications and declarations concerning interplay of the endocrine systems afford a good review even for those persons who are unusually well versed in this type of disease.

Several chapters are devoted to after-care which brings in a consideration of physical therapy. This will be of interest to surgeons although some of the views expressed may be controversial. Apparently the British method of postoperative follow up care is a little different from the American method in that the care is entrusted to physicians specializing in other fields. Of interest to the practitioner is the separate chapter on care after return to the home.

One disappointment in the chapter on postoperative complications has to do with vomiting, hiccups and abdominal distention. Most American surgeons are strong advocates of the Wangenstein method of suction drainage. Its value has been proved in

clinics too numerous to mention. Very little is said about this adjunct in this chapter. In addition the comment is made that the only drugs that are effective in abdominal distention are the derivatives of opium. A very serious question may be raised here in light of recent work which tends to suggest that the derivatives of opium might well be contraindicated. The giving of purges or enemas in this condition is also controversial but, as the general editors stated in their introduction, it would be difficult to get people to agree on all points.

In the section dealing with thrombosis and embolism it is interesting to note that the particular author is an advocate for the "walking treatment" of thrombophlebitis which may be a controversial point considering current opinion in many American clinics. The comments on prophylaxis of thrombosis and embolism are rather disappointing in that heparin is the only preparation that is even mentioned. It may be that this part of the article was prepared some time before the volume went to press but it appears that the average American surgeon would have devoted considerably more space not only to heparin but to dicumarol and to ligation of femoral veins. The evidence now at hand in this country cannot be denied in regard to the efficacy of several of these measures.

In other portions of the volume interesting sidelights on surgical practice are touched on briefly. These include such items as allergy and amebiasis as well as amyloidosis.

The chapter on amputations is as complete as is necessary and contains valuable information in regard to prosthesis and rehabilitation.

One of the strongest aspects of the entire volume is the section on anesthesia. This is well outlined and condensed and brings in the important points stressed by Lundy, McGill and other authorities. Regional and spinal anesthetic procedures are covered as fully as space would permit.

The chapter on artificial anus is brief enough to avoid argument but of necessity presents several pieces of apparatus which might raise some question in the minds of certain authorities. The experience in this country has been that there is no agreement about appliances and patent apparatus, and perhaps the less said the better.

A delightful surprise is the thorough discussion offered on appendicitis. After all the average surgeon who will be away from the large medical centers will be confronted by this problem perhaps more than by any other. The illustrations and suggestions, and the general outline bring out nothing particularly new but afford a clear résumé.

The author of the section on arteries has drawn heavily on anatomic studies and offers excellent illustrations in regard to the approach to various large vessels. The chances are that the occasional surgeon who has this volume handy can refer to it even in an emergency which this chapter suggests. There is included a discussion on aneurysm and fistula which of necessity is sketchy in places but at least offers a

picture of what the specialist can accomplish in ideal circumstances.

There is a rather long section on bone and joint surgery complete with suggestions for postoperative training including use of artificial limbs. This will be of great practical importance to isolated practitioners entrusted with the care of patients who need such training.

The section on asepsis and antisepsis is rather short, but implies a great deal more than space permits in the discussion. Fortunately the list of references for this part is rather complete and the serious student will be able to find fuller information with this list as a guide.

E. S. Jono, Jr

THE second volume in the series, *British Surgical Practice*, starts with the topic Backache and ends with Burns. It is difficult to review the entire volume in a short essay because of the wide variety of topics.

The several important chapters on bacteriology contain the necessary details, with a rather full out line of the important features. A discussion on penicillin coincides quite well with the accepted American views of today. Combined treatment with heparin and chemical agents is suggested in a short paragraph although it is not elaborated. This treatment has proved to be of considerable value in this country in certain infections. The sulfonamides are mentioned rather briefly but apparently are not held in as high regard as they still are in some parts of this country. There is a discussion on the anaerobic spore-bearing bacilli which is very timely in that these organisms must always be borne in mind. Now that the lessons of the war are receding into the back ground, it is well to call to mind some of the less common complications which cannot be overlooked. The usual sources of anaerobic infection are discussed and measures to overcome the complications resulting from such infections are mentioned as fully as space will allow. The importance of spores is emphasized and the types of wounds in which they are likely to be encountered are listed. In this regard there is a good discussion of the proper construction of an operating room as far as antisepsis and asepsis are concerned. The demonstrations of the apparent value of scrubbing of the hands for varying periods are somewhat primitive but nonetheless effective. The current authorities are all quoted and although the section on surgical technique is most brief there are enough good references for those who are seriously interested.

In a subsection entitled "Chemotherapy" there are several statements which should be subjected to challenge. An example is the impression one gets that the sulfonamides have little or no effect on gram-negative bacilli. It is still felt in American circles that the sulfonamides are definitely indicated occa-

sionally. Infections of the urinary tract with *Escherichia coli* still respond dramatically to sulfonamides, and there is good experimental evidence to show that peritonitis of the fecal type can be successfully combated with these preparations. In addition, the military doctors in the Pacific areas in World War II found that several of the dysentery-producing organisms were almost specifically susceptible to sulfadiazine. Fortunately this part of the text has a very thorough bibliography and there are arguments in support of most of the statements.

There are comments, with adequate illustration, in respect to "general management of the patient" which include discussion of the proper construction of beds, plaster jackets, and so forth. The inevitable problem of bedsores is discussed briefly. A group of miscellaneous biochemical tests are outlined, with a short discussion of their use, which will be of value to the physician who operates only occasionally and will probably also afford a rapid review for experts. There are a few sections dealing with complications, scarcely considered surgical, which the practitioner will encounter. Examples of these are bites and stings. Further in the text, there are other non-surgical topics, such as the blood forming organs, leucemias, blindness, and high and low blood pressure.

A very strong section of this volume is the detailed discussion on the urinary bladder as regards injuries and neurogenic disturbances. This leads very logically to a discussion of tumors and operative technique on the bladder which is sufficiently thorough to serve as a guide to the physician who occasionally operates.

More up to date, perhaps, than some parts of the book is the section on blood transfusion. There is a clear, concise outline on agglutination reactions, the Rh factor and so forth.

There is a rather prolonged section on bones and their pathology, which includes a discussion of bone grafting. This is a bit out of the field of the general practitioner and is probably much too sketchy for the orthopedic expert. Many of the cases cited and illustrations offered are most interesting from the standpoint of pathologic curiosities, but scarcely of prime importance from the standpoint of the general practitioner. If as the introduction to the first volume suggests, the book is to be used as a ready reference to the isolated practitioner many of the topics under discussion in the chapters on bone will merely be academic aids in classifying the case when the practitioner refers the patient to the large medical center for his definitive care.

There is a detailed section on brain surgery. Fortunately the greater part of this section is devoted to practical applications alone. Although the chapters are written by neurosurgical experts, the material covers problems that will confront the general surgeon and occasionally the practitioner. The greatest stress is laid upon emergency and temporizing procedures with clear outlines and illustrations to emphasize the practical applications. Implied and presumed restrictions are obvious as to where the physician who occasionally operates should stop. In-

(BRITISH SURGICAL PRACTICE. Under the general editorship of Sir Ernest Rackarbone, F.R.C.S., F.R.C.P. and J. Paterson Ross, M.S., F.R.C.S. Vol. London: Butterworth & Co., Ltd.; St. Louis: The C. V. Mosby Co., 1944.)

tably there is a discussion of brain tumor which is not particularly prolonged and which probably should stress a bit more the need for placing these patients in a category wherein they are to be cared for by experts only. Operations for decompression and for short-circuiting receive brief comment. The emergency treatment of lesions of the head is well outlined and there is a good discussion of surgical principles involved in cases of this type.

The section on carcinoma of the breast is rather short probably because most of the material is now well known even in remote places. The portion of this section dealing with pathology is rather too brief and there is little or no discussion of grading of malignancy which may be a reflection of the light in which that convenient method is held throughout the British Isles. One of the most important statements made in this chapter is the following: "Aspiration may be needed to confirm a diagnosis of a cyst, but the possibility that carcinoma may exist in the wall of a cyst must never be forgotten." In a discussion of radical mastectomy the indications and contraindications for the operation are much the same as those listed by authorities in the United States with one notable exception namely that of ulceration of the skin. Many authorities in the United States feel that radical mastectomy can still be accomplished with good results in the presence of some ulceration in certain cases. The conclusions about preoperative and postoperative roentgen therapy seem quite sound namely that radical operation first followed by roentgen treatment, will probably be best in a vast majority of cases. The author of this section touches upon simple mastectomy plus roentgen therapy. Some of the Continental surgeons now are swinging back to that treatment in a large percentage of their cases. The author still seems to feel that the radical procedure is preferable but is cognizant of the recent revival of the other method. Apparently some of the patients with far advanced disease are treated by means of simple mastectomy only as a palliative measure roentgen therapy being employed for obvious metastatic nodal tumors. Following this discussion there is a résumé of mastitis and infections of the breast which while brief is quite clear and to the point.

There is a short section on surgery of the lung as encountered in the treatment of bronchiectasis. Once again the question arises as to whether this type of surgical treatment is to be performed by the physician who occasionally operates or whether it might not be better to leave it to the thoracic surgeon who has all the accouterments for preoperative preparation and postoperative treatment.

E. S. JUDN JR.

THE two hundred and eighteen page monograph by Dr. Noel A. Gillespie entitled *Endotracheal Anaesthesia*¹ is a revised and enlarged second edition. It includes a section on anesthesia problems

peculiar to thoracic operations and the technique of tactile oral intubation with 12 additional illustrations of apparatus. There is a foreword by I. W. McGill, Ralph Walters and Arthur Guedel.

The work describes the historical aspects of the subject with meticulous care and discusses in detail the theoretical and practical aspects of endotracheal intubations. After a short dissertation on insufflation technique the remaining portion is devoted to endotracheal inhalation anesthesia. The elementary fundamental facts of anatomy physiology pharmacology and pathology are stated but not elaborated upon.

This book is a practical guide to a clinical skill. It will serve as a foundation upon which "may be built improvements in principle and technique which will make endotracheal anesthesia an even more useful aid than has been found at the present in the desire to bring help to surgeons and comfort and safety to patients."

Wider availability of endotracheal anesthesia depends upon an increased supply of medical men conversant with the facts and skilled by long experience in the technique of intubating the trachea. It is the author's hope that this monograph may thus enable more patients to reap the benefits accruing both to surgeons and anesthetists from tracheal intubation.

There is included an excellent bibliography and references that will enable any reader sufficiently interested to refer readily to the original sources.

MARY KARE

A SMALL 350 page volume *Symposium on Medicolegal Problems*¹ is of great interest and practical importance. It is a report of the medicolegal symposium which in the fall of 1945 was conducted jointly by the Institute of Medicine of Chicago and the Chicago Bar Association. It presents some of the problems which call for a joint effort of the two professions. Each of the subjects is presented first from the medical and then from the legal point of view by qualified representatives of the two professions. The discussion from the floor makes for lively reading.

There is a discussion of the conduct of the expert witness in court and the abuses of medical testimony with a suggested remedy in the form of disciplinary proceedings against any doctor or lawyer responsible for any irregularities in the presentation of such testimony. Any questionable testimony will be investigated by a committee of the Medical or Bar Association. The subject of artificial insemination is aired completely in a second discussion with all the implications considered in the open discussion. The medicolegal problems involved in the practice of pathology constitute a third chapter and many points of interest are brought up. Aside from a thorough discussion of

¹SYMPOSIUM ON MEDICOLEGAL PROBLEMS UNDER THE CO-SPONSORSHIP OF THE INSTITUTE OF MEDICINE OF CHICAGO AND THE CHICAGO BAR ASSOCIATION. Edited by Samuel A. Levinson, M.D. Phila. Philadelphia, London, Mostel et J. B. Lippincott Co., 1945.

ENDOTRACHEAL ANAESTHETICS. By Noel A. Gillespie, D.M.B.Ch., M.A.(Oxon.), M.D.(Wisc.), D.A.(R.C.S. Eng.). Madison, Wisconsin: The University of Wisconsin Press, 1945.

SURGICAL SPECIALTIES

Panel discussions on the surgical specialties will be held on Friday afternoon from 1:30 to 4:45 o'clock. The panels will be held concurrently in the following fields: urology, orthopedic surgery, neurological surgery, gynecology and obstetrics, thoracic surgery, and plastic surgery. Programs are shown on succeeding pages.

OPHTHALMOLOGY

An exceptionally interesting program is being planned for ophthalmologists, consisting of two evening sessions, three morning panel discussions from 9:00 to 10:30, and an evening session on Wednesday in which a combined program with the otorhinolaryngologists will be held.

Subjects for the Tuesday evening session will be "Tumors of the Eyelids and the Conjunctiva," "Partial Keratectomy and Diathermy Cantharization of the Ciliary Body for Glaucoma." At the Wednesday evening combined session the subject will be "Neoplasms of the Eyelids, Orbit, Nose and Accessory Sinuses: Treatment and Plastic Repair." Subjects for the Thursday evening session will be "The Use of Retrobulbar Alcohol Injection for Ocular Pain," "Retinal Detachment," and "Correlation of the Anatomic Factors Concerned in the Ophthalmoscopic Appearance of Retinal Hemorrhages."

The morning panel discussions will be on the following subjects: Surgical Management of (1) Acute Inflammatory Glaucoma, (2) Chronic Simple Glaucoma, (3) Congenital Glaucoma, on Tuesday; Congenital Cataract on Wednesday; and Surgery of the Oblique Muscles on Thursday.

OTORHINOLARYNGOLOGY

The program in otorhinolaryngology will consist of two evening meetings, an evening session on Wednesday in which a combined program with the ophthalmologists will be held, and three morning panel discussions from 10:45 to 12:15. The fact that the morning panel discussions are planned to follow those on ophthalmology will enable surgeons who combine these specialties in their practice to attend both sessions.

The subjects for the evening meetings will be as follows: On Tuesday, "Effects of Streptomycin on Eighth Nerve Function," "Anatomical Considerations in Eye Surgery," and "Chronic Laryngeal Stenosis," on Thursday, "Present Day Status of Fenestration Surgery," "Tumors of the Nasopharynx," "The Modern Management of Oro-antral Fistula," and "Surgical Treatment of Laryngeal Cancer." The subjects for the Wednesday evening joint session are listed under "Ophthalmology" and also on succeeding pages which carry the detailed programs.

SYMPOSIA ON CANCER

On Tuesday afternoon from 2:00 to 5:00 a Symposium on "Cancer Is Curable" will be held at which surgeons will report on series of cancer survivals without recurrence of from five to twenty five years, and the College will report the additions to its Archives of Cancer Cures.

On Wednesday afternoon from 2:00 until 5:00 o'clock a Symposium on Cancer with Dr. Grantley W. Taylor of Boston, chairman of the Cancer Committee, American College of Surgeons, presiding is scheduled. The subjects for discussion are: "Tumors of the Central Nervous System," "Cancer of the Stomach—A Survey of 1,004 Cases," "Lymphomas," "Early Diagnosis for Proper Treatment of Cancer of the Urinary Bladder," "Tumors of Parotid," and "Cancer of the Ovary." The list of subjects together with the speakers is published on page 374.

SYMPOSIUM ON FRACTURES AND OTHER TRAUMAS

Dr. Robert H. Kennedy of New York, chairman, Committee on Fractures and Other Traumas, will preside at the Symposium on Fractures and Other Traumas which will be held on Tuesday from 2:00 to 5:00 p.m. An interesting program is being developed under Dr. Kennedy's direction. The program appears on page 374.

HOSPITAL STANDARDIZATION CONFERENCE

The first formal session of the Clinical Congress will be the opening meeting of the twenty-seventh Hospital Standardization Conference at 10:00 o'clock on Monday morning, October 18. The preliminary plans for this meeting are outlined on a preceding page under the heading "General Assembly." The hospital conferences will continue on Monday afternoon with sessions following on Tuesday, Wednesday and Thursday mornings, afternoons, and evenings.

Hospital administrators, members of governing boards, medical staff members, heads of the various hospital departments and their personnel, nurses, dietitians, medical records librarians and many other persons directly concerned about hospital progress, will be interested in the discussions of current hospital problems.

Among the subjects which will be discussed at

the conferences will be the following: "New Developments in Medical Science which Affect Hospital Administration," "Office Facilities for Doctors in Relation to the Hospital," "Hospital Public Relations," "Discussion of Current Hospital Advances," "Approaching a Solution to our Nursing Problems," "Financial Relations with Patients and Doctors," "Problems of Small Hospitals," and "Progress Toward the Medical Center Concept." Tuesday evening will be devoted to a round table conference on Hospital Standardization. Wednesday evening to a forum for hospital trustees. Thursday evening to a forum on fundamental administrative problems with administrative interns and graduates of the schools of hospital administration as the participants and Wednesday afternoon to a joint session with the American Association of Medical Record Librarians.

Adding with the program are the following members of the Hospital Standardization Conference committee: Rita E. Heerman, superintendent, The California Hospital chairman; Paul C. Elliott, superintendent, Hollywood Presbyterian Hospital and President, Southern California Hospital Council; Alden B. Mills, administrator, Huntington Memorial Hospital, Pasadena; Sister Alphonsine, R.N., superintendent, St. Vincent's Hospital, Los Angeles; and Arthur J. Will, superintendent of charities, County of Los Angeles.

COMMITTEE ON ARRANGEMENTS

The Committee on Arrangements for the Clinical Congress in Los Angeles has been well organized and is actively functioning. The membership follows:

General Committee

Donald G. Tolleson, M.D., F.A.C.S., *Chairman*
 Hugh T. Jones, M.D., F.A.C.S., *Vice-Chairman*
 Harold Lincoln Thompson, M.D., F.A.C.S., *Secretary-Treasurer*
 Gilbert J. Thomas, M.D., F.A.C.S., *Represent of the College*
 E. Vincent Aubrey, M.D., F.A.C.S.
 Max W. Bay, M.D., F.A.C.S.
 J. MacKenzie Brown, M.D., F.A.C.S.
 Lawrence Chaffin, M.D., F.A.C.S.
 A. Ray Irvine, M.D., F.A.C.S.
 Maurice Kahn, M.D., F.A.C.S.
 W. E. MacPherson, M.D.
 B. O. Martinson, M.D.
 Louis J. Regan, M.D.
 Carl Roache, M.D., F.A.C.S.
 Stafford Warren, M.D.

Committee for the Southern California Chapter

Ray B. McCarty, M.D., F.A.C.S., *Riverdale*
 Meredith G. Beaver, M.D., F.A.C.S., *Redlands*
 Clarence E. Rees, M.D., F.A.C.S., *San Diego*
 Carl G. Johnson, M.D., F.A.C.S., *Long Beach*
 James H. Saint, M.D., F.A.C.S., *Santa Barbara*

Hospital Committee

The members of the hospital committee are listed on succeeding pages with the list of hospitals participating in the clinical program.

MEDICAL MOTION PICTURES

An appreciated feature of the Clinical Congress will again be the showing of medical motion pictures each day. The latest available pictures on surgery and related subjects will be presented. Special showings will be arranged of medical motion pictures in the fields of ophthalmology and otorhinolaryngology. Both sound and silent films will be shown, all of which will have been approved by the Committee on Motion Pictures. Some of the newer medical motion pictures now under production will be shown.

TECHNICAL AND SCIENTIFIC EXHIBITIONS

The Technical and Scientific Exhibits will occupy the Ballroom foyer, the Renaissance Room, and the Galleria of the Biltmore Hotel, according to present plans. Leading manufacturers of surgical instruments, x-ray apparatus, sterilizers, operating room lights, ligatures, dressings, hospital apparatus and supplies of all kinds and pharmaceuticals, and publishers of medical books will be represented.

ENTERTAINMENT FOR LADIES AND GUESTS

The Committee on Arrangements is planning a most interesting program for the wives and other guests of Fellows who are attending the Clinical Congress. Among the events planned are motor tours in and around Los Angeles to include such attractions as the Huntington Library, Griffith Park Planetarium, Olvera Street, Chinatown, visits to Hollywood studios and homes of motion picture stars, and radio broadcasts. Tickets to the broadcasts will be available upon request only at the registration desk at the Biltmore Hotel.

There will be a separate charge for each of the entertainment events. Each Fellow who registers in advance will receive a card listing the entertainment activities which he must check, if he is interested, and return the card accompanied by personal check to cover the total amount to Mrs. Verne C. Hunt, Box 95, San Marino, California.

ADVANCE REGISTRATION

Surgeons who wish to attend the Congress should register in advance. Under a new plan, advance registration will greatly expedite the procedure of registering.

No registration fee will be charged. Fellows whose dues are paid to December 31, 1947, for

endorsed Junior and Senior Candidates, the fee will be \$5.00. Non-Fellows who after individual consideration are permitted to register will pay a fee of \$10.00.

No registration fee will be required of initiates of the class of 1948.

HOTEL RESERVATIONS

It is desirable to make hotel reservations as early as possible because of the shortage of hotel rooms that prevails in Los Angeles as well as in other cities. In making these communications should be addressed to the Los Angeles Conven-

tion and Visitors Bureau care of the Los Angeles Chamber of Commerce, stating that you will be attending the Clinical Congress of the American College of Surgeons. All hotel reservations for the Clinical Congress are to clear through this Bureau. No correspondence should be sent directly to the hotels. A form for reservations was enclosed in the letter recently sent to Fellows. Choice of hotels may be designated. The hotels in Los Angeles require a deposit in advance.

There follows the list of member hotels, Convention and Visitors Bureau Los Angeles Chamber of Commerce.

CLINICAL CONGRESS PROGRAM IN BRIEF

Monday October 18

8:00-12:00 Clinics and Demonstrations—Local Hospitals
 10:00-12:30 General Assembly—Ballroom
 1:30-3:00 Panel Discussion—Philharmonic Auditorium
 2:00-4:00 Television, Surgical Specialties—Foyer Biltmore Bowl (Lower Level)
 2:00-5:00 Clinics and Demonstrations—Local Hospitals
 2:00-5:00 Hospital Conference—Ballroom
 2:00-5:00 Surgical Film Exhibition (General)—Biltmore Theater
 3:30-5:00 Panel Discussion—Philharmonic Auditorium
 8:15-10:30 Presidential Meeting—Philharmonic Auditorium

Tuesday October 19

8:00-12:00 Clinics and Demonstrations—Local Hospitals
 8:30-12:30 Forum on Fundamental Surgical Problems—Philharmonic Auditorium
 8:30-12:30 Forum on Fundamental Surgical Problems—Ballroom

9:00-10:30 Panel Discussion Ophthalmology—Conference Room No. 1
 9:30-12:30 Hospital Conference—Music Room
 9:30-12:30 Surgical Film Exhibition (General)—Biltmore Theater
 10:00-12:00 Television General Surgery—Foyer Biltmore Bowl
 10:45-12:15 Panel Discussion—Otorhinolaryngology—Conference Room No. 1
 1:30-3:00 Panel Discussion—Philharmonic Auditorium
 2:00-4:00 Television Surgical Specialties—Foyer Biltmore Bowl
 2:00-4:00 Surgical Film Exhibition (L.E.N.T.)—Conference Room No. 1
 2:00-5:00 Hospital Standardization Conference—Music Room
 2:00-5:00 Symposium Cancer Is Curable—Ballroom
 2:00-5:00 Symposium on Fractures and other Traumas—Biltmore Theater
 3:30-5:00 Panel Discussion—Philharmonic Auditorium

- 7 00-8 00 Surgical Film Exhibition (E.E.N.T.)—Conference Room No. 1
 8 00-9 30 Hospital Conference—Music Room
 8 00-9 30 Scientific Session, General Surgery—Philharmonic Auditorium
 8 00-10 30 Scientific Session, Ophthalmology—Conference Room No. 1
 8 00-9 30 Scientific Session Otorhinolaryngology—Conference Room No. 5

Wednesday October 20

- 8 00-9 00 Meeting of Cancer Committee—Conference Room No. 6
 8 00-9 00 Clinics and Demonstrations—Local Hospitals
 8 30-9 30 Forum on Fundamental Surgical Problems—Ballroom
 8 30-9 30 Forum on Fundamental Surgical Problems—Philharmonic Auditorium
 9 00-9 30 Panel Discussion—Ophthalmology—Conference Room No. 1
 9 00-9 00 State and Provincial Executive Committees—Engineers' Club
 9 30-9 30 Hospital Conference—Music Room
 9 30-9 30 Surgical Film Exhibition (General)—Biltmore Theater
 9 00-9 00 Television, General Surgery—Foyer Biltmore Bowl (Lower Level)
 10 00-10 00 State and Provincial Credentials Committees and Committees on Applicant and Judiciary Committees.
 4 15-5 15 Panel Discussion, Otorhinolaryngology—Conference Room No. 1
 9 00-9 00 Luncheon—Meeting of Board of Governors.
 3 30-4 30 Panel Discussion—Philharmonic Auditorium
 4 00-4 00 Surgical Film Exhibition (E.E.N.T.)—Conference Room No. 1
 4 00-4 00 Television Surgical Specialties—Foyer Biltmore Bowl (Lower Level)
 4 00-4 00 Symposium on Cancer—Ballroom
 4 00-4 00 Surgical Film Exhibition (General)—Biltmore Theater
 10 00-10 00 Hospital Conference—Music Room
 3 30-4 30 Panel Discussion—Philharmonic Auditorium
 3 30-4 30 Meeting of National and Regional Fracture Committees
 7 00-8 00 Surgical Film Exhibition (E.E.N.T.)—Conference Room No. 1
 8 00-9 00 Combined Session, Ophthalmology and Otorhinolaryngology—Conference Room No. 1
 8 00-9 30 Scientific Session, General Surgery—Philharmonic Auditorium
 8 00-9 30 Hospital Conference—Music Room

Thursday October 21

- 8 00-9 00 Clinics and Demonstrations—Local Hospitals
 8 30-9 30 Forum on Fundamental Surgical Problems—Ballroom
 8 30-9 30 Forum on Fundamental Surgical Problems—Philharmonic Auditorium

- 9 00-9 30 Panel Discussion, Ophthalmology—Conference Room No. 1
 9 30-9 30 Hospital Conference—Music Room
 10 00-10 00 Television, General Surgery—Foyer Biltmore Bowl
 1 45-2 15 Panel Discussion, Otorhinolaryngology—Conference Room No. 1
 2 30-2 45 Adjourned Meeting, Governors—Ballroom
 2 45-3 00 Annual Meeting, Fellows—Ballroom
 3 00-4 00 Television, Surgical Specialties—Foyer Biltmore Bowl
 3 00-3 00 Hospital Conference—Music Room
 3 30-4 30 Surgical Film Exhibition (General)—Biltmore Theater
 3 00-3 00 Symposium, Graduate Training in Surgery—Ballroom
 3 30-4 00 Panel Discussion—Philharmonic Auditorium
 3 00-4 00 Committee on The Library—Conference Room No. 6
 6 00-8 00 Dinner for Committee on Fractures and Other Traumas and Chairmen, Regional Committees—Engineers' Club
 7 00-8 00 Surgical Film Exhibition (E.E.N.T.)—Conference Room No. 1
 8 00-9 00 Hospital Conference—Music Room
 8 00-10 30 Scientific Session—General Surgery—Philharmonic Auditorium
 8 00-9 30 Scientific Session—Ophthalmology—Conference Room No. 1
 8 00-9 30 Scientific Session—Otorhinolaryngology—Conference Room No. 8

Friday October 22

- 8 00-9 00 Clinics and Demonstrations—Local Hospitals
 8 30-9 30 Forum on Fundamental Surgical Problems—Ballroom
 8 30-9 30 Forum on Fundamental Surgical Problems—Philharmonic Auditorium
 9 30-9 30 Surgical Film Exhibition (E.E.N.T.)—Biltmore Theater

 10 30-11 30 Surgical Film Exhibition (General)—Biltmore Theater
 3 00-3 15 Assembly of Initiates—Temple, Baptist Church
 3 45-4 15 Panel Discussions for each of the following: Gynecology and Obstetrics—Conference Room No. 1
 Plastic Surgery—Ballroom
 Neurological Surgery—Conference Room No. 1
 Thoracic Surgery—Engineers' Club
 Urology—Conference Room No. 9
 Orthopedic Surgery—Biltmore Theater
 10 00-10 00 Television, Surgical Specialties—Foyer Biltmore Bowl
 9 00-9 00 Clinics and Demonstrations—Local Hospitals
 7 30-8 00 Assembly of Initiates for Processional—Temple Baptist Church
 8 5 100 Convocation—Philharmonic Auditorium

EVENING SCIENTIFIC SESSIONS

GENERAL SURGERY

Tuesday 8 00-10.30 p m

Symposium on Malignant Lesions of the Thyroid Gland

Histologic Types of Thyroid Carcinoma and Their Clinical Significance FRANK W. FOOTE, M.D., New York.
 Aberrant Thyroid. BRIEN T. KING, M.D., Seattle.
 Malignancy in Nodular Goiter WARREN H. COLE, M.D., Chicago.
 Radioactive Iodine for the Treatment of Thyroid Disease Including Carcinoma MYRON PRINZMETAL, M.D., Los Angeles.

Wednesday 8 00-10 30 p m

Fracture Oration. Colles' Fracture. HENRY C. MARBLE, M.D., Boston

Symposium on Endometriosis

Etiology of Endometriosis. BROOKS RANNEY, M.D., Chicago
 Surgical Procedures Involved in the Treatment of Endometriosis VIRGIL S. COUNSELLER, M.D., Rochester, Minnesota.
 The Medical Treatment and Significance of Endometriosis JOE V. MEIGS, M.D., Boston

Thursday 8 00-10 30 p m

Symposium on Surgery of the Heart and Great Vessels

Surgical Treatment of Pulmonic Stenosis ALFRED BLALOCK, M.D., Baltimore.
 The Surgical Treatment of Constrictive Pericarditis. EMILE F. HOLMAN, M.D., San Francisco.
 The Surgery of Patent Ductus Arteriosus JOHN C. JONES, M.D., Los Angeles.
 Treatment of Coarctation of the Aorta. ROBERT E. GROSS, M.D., Boston.

OPHTHALMOLOGY

Tuesday 8 00-10 30 p m

Tumors of the Eyelids and the Conjunctiva. MICHAEL J. HOGAN, M.D., San Francisco
 Partial Keratectomy GEORGE L. KILGORE, M.D., San Francisco
 Diathermy Cantharization of the Ciliary Body for Glaucoma. SAMUEL J. MEYER, M.D., Chicago

Thursday 8 00-10 30 p m

The Use of Retrobulbar Alcohol Injection for Ocular Pain ALFRED E. MAUMENEY, M.D., Baltimore.
 Retinal Detachment. DOHRMANN K. FISCHEL, M.D., San Francisco
 Correlation of the Anatomic Factors Concerned in the Ophthalmoscopic Appearance of Retinal Hemorrhages
 HOMER E. SMITH, M.D., Salt Lake City

OTORHINOLARYNGOLOGY

Tuesday 8 00-10 30 p m

Effects of Streptomycin on Eighth Nerve Function. PAGE NORTHINGTON, M.D., Oakland.
 Anatomical Considerations in Ear Surgery J. BROWN FARRIOR, M.D., Tampa.
 Chronic Laryngeal Stenosis. JOHN B. ERICH, M.D., Rochester, Minnesota

Thursday 8 00-10 30 p m

Present Day Status of Fenestration Surgery LEIGHTON F. JOHNSON, M.D., Boston.
 Tumors of the Nasopharynx. HARRY C. ROSENBERGER, M.D., Cleveland.
 The Modern Management of Oro-Antral Fistula RICHARD THOMAS BARTON, M.D., Beverly Hills.
 Surgical Treatment of Laryngeal Cancer CHEVALIER L. JACKSON, M.D., Philadelphia.

COMBINED SESSION—OPHTHALMOLOGY—OTORHINOLARYNGOLOGY

PANEL DISCUSSION

Wednesday 8:00-10:30 p.m.

Neoplasms of the Eyelids, Orbit, Nose and Accessory Sinuses: Treatment and Plastic Repair.

Moderator GORDON B. NEW, M.D., Rochester, Minnesota.

Collaborators: AUBREY G. RAWLIN, M.D., San Francisco; EDMUND B. SPAETH, M.D., Philadelphia;
JOHN B. ERICH, M.D., Rochester, Minnesota; MICHAEL J. HOGAN, M.D., San Francisco.

PANEL DISCUSSIONS

GENERAL SURGERY

Monday 1:30-3:00 p.m.

Acute Renal Failure in Surgical Patients

Moderator: FREDERICK A. COLLIER, M.D., Ann Arbor

Collaborators: CHARLES D. CREEVY, M.D., Minneapolis; ERNEST E. MUTHHEAD, M.D., Dallas; WILLIAM
O. RUSSELL, M.D., Santa Barbara.

Monday 3:30-5:00 p.m.

Tumors of the Mouth, Jaw and Face

Moderator: GORDON B. NEW, M.D., Rochester, Minnesota.

Collaborators: LOUIS T. BYARS, M.D., St. Louis; J. ELLIOTT SCARBOROUGH, JR., M.D., Atlanta;
ERNEST M. DALAND, M.D., Boston.

Tuesday 1:30-3:00 p.m.

Late Lying Malignant Lesions of the Bowel

Moderator: FRED W. RANKIN, M.D., Lexington.

Collaborators: R. KENNEDY GILCHRIST, M.D., Chicago; THOMAS E. JONES, M.D., Cleveland; JEROME
GRAY, M.D., Toronto.

Tuesday 3:30-5:00 p.m.

Evaluation of Lateral Flexion in Relation to Surgery

Moderator: NATHAN A. WOMACK, M.D., Iowa City

Collaborators: EVERETT I. EVANS, M.D., Richmond; ARTHUR H. BLAKEMORE, M.D., New York;
JESSE L. BOLLMAN, M.D., Rochester, Minnesota.

Wednesday 1:30-3:00 p.m.

Peripheral Arterial Disease

Moderator: ALTON OCHSNER, M.D., New Orleans.

Collaborators: NORMAN E. FREEMAN, M.D., San Francisco; I. RIDGEWAY TRIMBLE, M.D., Baltimore;
ROBERT R. LINTON, M.D., Boston.

Wednesday 3:30-5:00 p.m.

Ulcerative Colitis

Moderator: HENRY W. CAYE, M.D., New York.

Collaborators: ALBERT J. SULLIVAN, M.D., New Orleans; CLARENCE DENNIS, M.D., Minneapolis;
CLAUDE F. DIXON, M.D., Rochester, Minnesota.

Thursday 3:30-5:00 p.m.

Isotopes in Surgery

Moderator: GEORGE M. CURTIS, M.D., Columbus.

Collaborators: EARL R. MILLER, M.D., San Francisco; JOSEPH G. HAMILTON, M.D., Berkeley; GUYTON
COPE, M.D., Boston; BEVERLY C. SMITH, M.D., New York.

SURGICAL SPECIALTIES, Friday 1 30-4.55 p m

UROLOGY

Moderator: REED M. NESBITT M.D. Ann Arbor

Present Day Management of Urinary Tract Infections

Collaborators GRAYSON CARROLL, M.D. St. Louis WILLOUGHBY E. KITTREDGE M.D. New Orleans
GILBERT J. THOMAS M.D. Beverly Hills.

The Clinical Management of Branched Renal Calculi

Collaborators JAMES T. PRIESTLEY M.D. Rochester Minnesota RUBIN H. FLOCKS M.D. Iowa City
THOMAS E. GIBSON M.D. San Francisco

ORTHOPEDIC SURGERY

Moderator JOHN C. WILSON M.D. Los Angeles

Mechanical Derangements of the Knee Joint

Collaborators DOUGLAS D. TOFFELMAYER M.D. Oakland FRANCIS J. COX, M.D. San Francisco
FRANCIS E. WEST M.D. San Diego

Fractures About the Hip

Collaborators J. SMITH NORMAN M.D. Pueblo JOHN J. LOUTZENHEISER, M.D. San Francisco JAMES
K. STACK M.D. Chicago

NEUROLOGICAL SURGERY

Moderator HOWARD C. NAFFZIGER M.D. San Francisco

Cerebral Angiography

Collaborators CARL F. LIST M.D. Grand Rapids EDWIN B. BOLDREY M.D., San Francisco EARL
R. MILLER, M.D. San Francisco

GYNECOLOGY AND OBSTETRICS

Moderator JOHN C. BURCH, M.D. Nashville.

Hysterectomy Physiological Considerations—Indications

Collaborators LANGDON PARSONS M.D. Boston CONRAD G. COLLINS, M.D. New Orleans R.
GLENN CRAIG, M.D. San Francisco KARL H. MARTELOFF M.D. Portland.

Hysterectomy Technical Considerations—Complications

Collaborators (Same as above)

THORACIC SURGERY

Moderator FRANK S. DOLLEY M.D. Los Angeles

Diagnosis and Surgical Treatment by Pulmonary Resection for Carcinoma Bronchiectasis and Tuberculosis

Collaborators EVARTS A. GRAHAM M.D. St. Louis FRANK B. BERRY M.D. New York HERBERT C.
MAIER, M.D. New York.

Surgery of the Esophagus

Collaborators RALPH H. ADAMS M.D. Louisville LYMAN A. BREWER III M.D. Los Angeles
JOHN W. STRIEDER, M.D. Boston

PLASTIC SURGERY

Moderator TRUMAN G. BLOCKER, JR. M.D., Galveston.

Congenital Facial Deformities

Collaborators DOUGLAS W. MACOMBER M.D. Denver WILLIAM S. KISKADDEN M.D., Los Angeles
THOMAS D. CROMIN M.D. Houston WALLACE H. STEFFENSEN M.D. Grand Rapids.

Burn Contractures of the Extremities

Collaborators GEORGE V. WEBSTER M.D. Pasadena GERALD B. O'CONNOR M.D. San Francisco
LOUIS T. BYARS M.D., St. Louis NATHANIEL B. SOUDERBERG M.D. Phoenixville Pennsylvania

OPHTHALMOLOGY

Tuesday 9:00-10:30 a m

Surgical Management of Glaucoma

Moderator A. RAY IRVINE, M.D. Los Angeles.

Collaborators HAROLD L. GOSS M.D., Seattle ROBERT A. SHAFER M.D. San Francisco J. HEWITT
JUDD M.D., Omaha.

Wednesday 9:00-10:30 a.m.

Congenital Cataract

Moderator OTTO BARKAN, M.D., San Francisco.

Collaborators S. RODMAN IRVING, M.D., Los Angeles; HAROLD F. WHEALMAN, M.D., Los Angeles;
RAYMOND J. NUTTING, M.D., Oakland.

Thursday 9:00-10:30 a.m.

Surgery of the Oblique Muscles

Moderator C. ALLEN DICKEY, M.D., San Francisco

Collaborators OWYEN H. ELLIS, M.D., Los Angeles; AVERY MORLEY HICKS, M.D., San Francisco;
ALFRED R. ROBBINS, M.D., Los Angeles

OTORHINOLARYNGOLOGY

Tuesday 10:45 a.m.-12 15 p.m.

Rehabilitation of the Hard of Hearing

Moderator WALTER P. WORK, M.D., San Francisco

Collaborators HOWARD P. HOUSE, M.D., Los Angeles; S. RICHARD SILVERMAN, M.D., St. Louis;
HAROLD M. E. BOYD, M.D., Los Angeles.

Wednesday 10:45 a.m.-12 15 p.m.

The Preparation of the Surgical Patient and Post-Operative Care

Moderator COLBY HALL, M.D., Los Angeles.

Collaborators VICTOR GOODHILL, M.D., Los Angeles; CHARLES F. MCCUSKEY, M.D., Los Angeles;
HAROLD OWENS, M.D., Los Angeles.

Thursday 10:45 a.m.-12 15 p.m.

Diseases of the Esophagus

Moderator ALDEN H. MILLER, M.D., Los Angeles.

Collaborators SIMON JENBERG, M.D., Los Angeles; LEWIS F. MORRISON, M.D., San Francisco;
AMBROSE S. CHURCHILL, M.D., Los Angeles.

SYMPOSIUM ON FRACTURES AND OTHER TRAUMAS

Tuesday 2:00-5:00 p.m.

ROBERT H. KENNEDY, M.D., F.A.C.S., New York, Chairman, Committee on Fractures and Other Traumas.
Presiding

Avulsions of the Skin. CARLETON MATTHEWSON, JR., M.D., F.A.C.S., San Francisco.

Secondary Closure of Wounds. HARRY C. BLAIR, M.D., F.A.C.S., Portland.

Care of Acute Amputations of the Fingers. WALTER C. GRAHAM, M.D., F.A.C.S., Santa Barbara.

Fractures of the Lower End of the Humerus in Children. JOHN C. WILSON, M.D., F.A.C.S., Los Angeles.

Acute Arterial Emergencies. JERR W. LORD, JR., M.D., F.A.C.S., New York.

Evaluation of Principles Concerned in Management of Trauma to the Kidney. LAZARUS A. ORSKIN, M.D.,
F.A.C.S., New York.

SYMPOSIUM ON CANCER

Wednesday 2:00-5:00 p.m.

GRANTLEY W. TAYLOR, M.D., F.A.C.S., Boston, chairman, Cancer Committee, American College of Surgeons, presiding.

Tumors of the Central Nervous System. EDWIN B. BOLDREY, M.D., F.A.C.S., San Francisco, assistant clinical professor of surgery, University of California Medical School.

Cancer of the Stomach: A Survey of 1004 Cases. STANLEY E. LAWTON, M.D., F.A.C.S., Chicago, assistant professor of surgery, University of Illinois (Rush) College of Medicine.

Lymphomas. SIDNEY FARNER, M.D., Boston, assistant professor of pathology, Harvard University Medical School.

Early Diagnosis for Proper Treatment of Cancer of Urinary Bladder. GILBERT J. THOMAS, M.D., F.A.C.S., Beverly Hills, associate clinical professor of surgery (urology), University of Southern California School of Medicine.

Tumors of Parotid DANIEL P. SLAUGHTER, M.D. F.A.C.S. Chicago assistant professor of surgery University of Illinois College of Medicine.
 Cancer of the Ovary JOSE V. MEZOS, M.D. F.A.C.S. Boston clinical professor of gynecology Harvard University Medical School

PRESIDENTIAL MEETING

Monday 8 15-10 30 p.m.—The Philharmonic Auditorium

ARTHUR W. ALLEN, M.D. F.A.C.S. Boston President, American College of Surgeons Presiding
 Processional—Officers, Regents and Distinguished Guests

Invocation

Address of Welcome

DOUGLAS G. TOLLEFSON, M.D. F.A.C.S., Los Angeles

Chairman, Committee on Arrangements

Introduction of Distinguished Guests

IRVIN ABELL, M.D. F.A.C.S. Louisville

Chairman, Board of Regents

Address of the Retiring President Looking Forward

ARTHUR W. ALLEN, M.D.

Inauguration of Officers

Presented by THOMAS E. JONES, M.D., F.A.C.S. Cleveland

Retiring First Vice President

President DALLAS B. PREMISTER, M.D. F.A.C.S. Chicago

First Vice President HOWARD A. PATTERSON, M.D. F.A.C.S. New York

Second Vice President CARL H. MCCASKEY, M.D. F.A.C.S. Indianapolis

The Third Martin Memorial Lecture Some Aspects of the Development of Intrathoracic Surgery

CLARENCE CRAWFORD, M.D. Stockholm Sweden Professor of Surgery Karolinska Mediko-kirurgiska Institutet

CONVOCATION

Friday 8 15-10 30 p.m.—The Philharmonic Auditorium

DALLAS B. PREMISTER, M.D. F.A.C.S. Chicago President, American College of Surgeons Presiding
 Processional—Initiates, Officers, Regents and Distinguished Guests

Invocation

Presentation of Initiates for Fellowship

IRVIN ABELL, M.D., F.A.C.S. Louisville

Chairman, Board of Regents

Fellowship Pledge. Recital by Initiates

Conferring of Fellowships by the President

DALLAS B. PREMISTER, M.D.

Conferring of Honorary Fellowships

The President

Fellowship Address The Physicist Meets the Doctor

LEE A. DUBRIDGE, Ph.D., Pasadena, California

President, California Institute of Technology

Recessional

Reception by the Officers and Regents for the Initiates and Fellows

ANNUAL MEETING, BOARD OF GOVERNORS OF THE COLLEGE

Wednesday 12 15-2 00 p.m.—Ballroom The Biltmore Hotel

DALLAS B. PREMISTER, M.D. F.A.C.S. Chicago President, American College of Surgeons Presiding

Statement by the Chairman of the Board of Regents

IRVIN ABELL, M.D. F.A.C.S. Louisville

Brief Reports on the Activities, Problems, and Progress of the American College of Surgeons
 ARTHUR W. ALLEN, M.D., F.A.C.S., Boston, Immediate Past President
 FREDERICK A. COLLIER, M.D., F.A.C.S., Ann Arbor, Regent
 Discussion by Governors and Regents

ADJOURNED MEETING BOARD OF GOVERNORS OF THE COLLEGE

Thursday 1:30 p.m. — Ballroom, The Biltmore Hotel

DALLAS B. PREMISTER, M.D., F.A.C.S., Chicago, President, American College of Surgeons, Presiding
 Report of Committee on Nominations to the Board of Governors

ANNUAL MEETING FELLOWS OF THE COLLEGE

Thursday 1:45 3:00 p.m. — Ballroom, The Biltmore Hotel

DALLAS B. PREMISTER, M.D., F.A.C.S., Chicago, President, American College of Surgeons, Presiding
 Report of Committee on Nominations

Election of Officers and Governors of the College

Report of the Treasurer

DALLAS B. PREMISTER, M.D., Chicago, Treasurer

EDWARD G. SANDROK, Comptroller

Cancer Committee

GRANTLEY W. TAYLOR, M.D., F.A.C.S., Boston, Chairman

Committee on Fractures and Other Traumas

ROBERT H. KENNEDY, M.D., F.A.C.S., New York, Chairman

Committee on Graduate Training in Surgery

FREDERICK A. COLLIER, M.D., F.A.C.S., Ann Arbor, Chairman

Hospital Department

Hospital Standardization

MALCOLM T. MACLACHERN, M.D., Associate Director

Graduate Training in Surgery

PAUL S. FERGUSON, M.D., Assistant Director, Hospital Activities

GEORGE H. MILLER, M.D., Director of Educational Activities

Sectional Meetings

MALCOLM T. MACLACHERN, M.D., Associate Director

H. PRATHER SAUNDERS, M.D., F.A.C.S., Associate Director

Credential Department

a. Credentials Committee

b. Committee on Applicants

c. Committee on History Reviews

H. PRATHER SAUNDERS, M.D.

Clinical Research

Medical Service in Industry

BOWMAN C. CROWELL, M.D., Associate Director

 White Memorial Hospital, Los Angeles—Clarence E. Stafford, M.D., F.A.C.S.

CLINICS IN LOS ANGELES AND VICINITY HOSPITALS

THE CALIFORNIA HOSPITAL, LOS ANGELES

Tuesday

8:00-12:00. *General Surgery* Operative Clinics
 Gastrointestinal Surgery—Vagotomy and Gastroenterostomy JACK M. FARRIS and ASSOCIATES.
 Two Team Abdominal Perineal. MALCOLM R. HILL and ASSOCIATES.
 Gastric Resections. WILLIAM F. QUINN, NORMAN L. CARDEY

Wednesday

8:00-12:00. *General Surgery* Operative Clinics
 Carcinomas of Face, Neck, and Breast. LOS ANGELES Tumor Institute Staff
 Carcinoma of the Stomach. LEWIS A. ALERSEN
 Thoracic Surgery Operative Clinic
 Carcinoma of Lung. LYMAN A. BREWER and ASSOCIATES.

Thursday

8:00-12:00. *General Surgery* Operative Clinics
 Lesions of Thyroid. O. DALE LLOYD
 Cholecystic Disease. WILLIAM HENRY OLDS and ASSOCIATES.
 Hernioplasty. FREDERICK W. LEIX and ANTON LAUBER-SCHMIDT.

Friday

8:00-12:00. *Obstetrics and Gynecology* Operative Clinics
 Total Hysterectomy. DONALD G. TOLLEFSON and ASSOCIATES.
 Vaginal Hysterectomy. PAULA HORN and ASSOCIATES.
 Total Hysterectomy. WILLIAM H. BROWNFIELD and ASSOCIATES.

Low Cervical Section and other Gynecological Procedures. RALPH J. THOMPSON, GEORGE W. HEWITT and AARON NEAL WEBB

CEDARS OF LEBANON HOSPITAL, LOS ANGELES

Tuesday

10:00-12:00. *General Surgery* Operative Clinic. Thyroidectomy. MAURICE G. KAHN, MAX W. BAY
 10:00-12:00. *Gynecology* Operative Clinic: Selected cases. EMIL J. KRAHLICK.
 10:00-12:00. *Genitourinary Surgery* Operative Clinic: Selected cases. JAMES STEINBERG.

Wednesday

10:00-12:00. *General Surgery* Operative Clinic. Smithwick operation. MARCUS H. RABWIN
 10:00-12:00. *Neurosurgery* Operative Clinic. Selected cases. TRACY PUTNAM.

Thursday

10:00-12:00. *General Surgery* Operative Clinic. Abdominal surgery. ISAAC Y. OLCH.
 10:00-12:00. *Gynecology* Operative Clinic. Selected cases. JOSEPH M. HARRIS, LEON KROHN
 10:00-12:00. *Genitourinary Surgery* Operative Clinic: Selected cases. JAMES STEINBERG

Friday

10:00-12:00. *General Surgery* Operative Clinic: Selected cases. SAM S. HEINTHOFF
 10:00-12:00. *Thoracic Surgery* Operative Clinic: Selected cases. ALFRED GOLDMAN

Tuesday through Friday

10:00-1:00. *General Surgery* Nonoperative Clinics
 Smithwick Operation, Colectomy; Gall Bladder: Thyroid
 Roentgenology: Pathology. MARCUS H. RABINOWITZ,
 DAVID H. ROSENTHAL, MAX W. BAY, ISAAC Y. OLICK,
 Members of Thyroid Committee, EDGAR F. FREEDMAN,
 N. I. RICHMAN.

CHILDREN'S HOSPITAL, LOS ANGELES

Monday

Thoracic Surgery Operative Clinics
 Blacklock Operation: Bronchoscopies. JOHN C. JONES.
Oral Surgery Operative Clinics
 Cleft Palates, Cleft Lips. EMIL F. THOLEN.
Orthopedic Surgery Operative Clinics.
 Hip Fusion: Triple Arthrodesis: Biopsy of Knee. JOHN
 WILSON.

10:00-1:00. *Thoracic Surgery* Nonoperative Clinics
 Patent Ductus Arteriosus: The Blacklock Operation.

Tuesday

Otolaryngology Operative Clinics
 Tonsillectomy and Adenoidectomy: Mastoidectomy
 ALDEN MILLER.
Plastic Surgery Operative Clinics
 Pudgett: Grafts: Reconstruction: Ears, Excision of Nerve
 in Graft. WILLIAM S. KISSKADEN.
Ophthalmology Operative Clinics.
 Recession and Resection: Tuck and Recession, O'Connor
 Clinch: Pious, Molau. A. RAY IVERSON.
 10:00-1:00. *Plastic Surgery* Nonoperative Clinic
 Immediate and Late Results Obtained in the Treatment
 of Burns.

Wednesday

General Surgery Operative Clinics
 Herniorrhaphy: Orchiopexy, Appendectomy: Thyro-
 glandular Cyst. LAWRENCE CHAFFIN.
Thoracic Surgery Operative Clinics.
 Coarctation, Patent Ductus. JOHN C. JONES.
 10:00-1:00. *General Surgery* Nonoperative Clinic
 General Pediatric Problems in Childhood.

Thursday

Genitourinary Surgery Operative Clinics
 Nephrectomy: Bladder Neck Resection: Cystoscopies.
 O. W. BUTLER.
Orthopedic Surgery Operative Clinics.
 Spinal Fusion: Arthrodesis (Britton type). JOHN C.
 WILSON.
Proctology Operative Clinic
 Rectovaginal Fistula. HERBERT E. SMILEY.
Endoscopy Operative Clinics
 Bronchoscopy: Laryngoscopy. ALDEN MILLER.
Neurosurgery Operative Clinics.
 Cerebellar Exploratory: Choroid Plexectomy: Boneflap.
 CARL W. RABIN.
 10:00-1:00. *Orthopedic Surgery* Nonoperative Clinic
 Clinical Diagnostic Problems.
Neurology Nonoperative Clinic
 Brain Tumors in Childhood.

Friday

Otolaryngology Operative Clinic
 Tonsillectomy and Adenoidectomy. ALDEN MILLER.
General Surgery Operative Clinics
 Pyloroplasty: Herniorrhaphy. WILLIAM J. NORRIS,
 J. MRS. NORTON NICHOLS.

Ophthalmology Operative Clinics.
 Recession and Resection: Excision: Pious. A. RAY
 IVERSON.
 11:00-12:00. *Ophthalmology* Nonoperative Clinic
 Squint and Muscle Surgery.
Otolaryngology Nonoperative Clinic:
 Acute Obstructive Laryngitis.

FRENCH HOSPITAL, LOS ANGELES

Wednesday

10:30-1:00. *Tumor Surgery* Nonoperative Clinic: Re-
 local Cancer: Surgery of Head and Neck—sides—ears.
 SAM L. PERLIT.
 10:30-1:00. *Tumor Surgery* Nonoperative Clinic: Com-
 bined Attack of Cancer of Head and Neck—sides—
 ears. CLYDE K. EMERY.
 1:00-1:30. *Tumor Surgery* Nonoperative Clinic: In-
 situ Tumors of Neck—sides. ALICE POLLAK.
 1:30-2:00. *General Surgery* Nonoperative Clinic: In-
 situ Tumors of Neck—sides. ALICE POLLAK.
 2:00-2:30. *General Surgery* Nonoperative Clinic: In-
 situ Tumors of Neck—sides. ALICE POLLAK.

Wednesday Afternoon

 FRED GASPARD, IVO LOTTICE, VICTOR CHAIK,
 PIERRE PAUL VIDOLE.

HOLLYWOOD PRESBYTERIAN HOSPITAL—
OLMISTED MEMORIAL

Tuesday

8:00-1:00. *Tumor Surgery* Nonoperative Clinic:
 Cases Presented with Followup. C. IRVING WATSON
 and STAFF.

Wednesday

8:00-1:00. *Tumor Surgery* Operative Clinics:
 Radical Mastectomy with Cancer. C. IRVING
 WATSON and STAFF.
 8:00-1:00. *Genitourinary Surgery* Operative Clinic:
 Urological Surgery. STAFF.
 8:00-1:00. *General Surgery* Operative Clinics:
 Thyroidectomy: Gastric Resection: Lobectomy: Stomach
 10:00-1:00. *General Surgery* Nonoperative Clinic:
 Nonsurgical treatment for Genital Reluctance including
 Urinary Incontinence with Exhibit. ARTHUR J.
 MCKENNEY.
 1:00-2:00. *General Surgery* Nonoperative Clinic:
 Traumatic Injuries to Abdomen. DONALD C. COLEMAN.

Thursday

8:00-1:00. *General Surgery* Operative Clinics:
 Selected Cases. STAFF.
 9:00-1:00. *Plastic Surgery* Operative Clinics:
 Mastopexy: HERBERT OTTO BAKER.
 10:00-1:00. *Plastic Surgery* Nonoperative Clinic:
 Demonstration: Plastic Technique. HERBERT OTTO
 BAKER.

HOSPITAL OF THE GOOD SAMARITAN,
LOS ANGELES

Tuesday

8:00-1:00. *General Surgery* Operative Clinic: Selected
 Cases. LAWRENCE CHAFFIN, WILLIAM J. NORRIS.
 8:00-1:00. *Thoracic Surgery* Operative Clinic: Selected
 Cases. JOHN C. JONES.
 8:00-1:00. *Neurosurgery* Operative Clinic: Selected
 Cases. GEORGE H. PATTERSON.

- Results of Vagotomy. Los Angeles County General Hospital. HARRY C. PROUT.
- General Surgery** Nonoperative Clinic
Causes of Upper Gastro-Intestinal Bleeding (Illustrated) HAROLD LINCOLN THOMPSON.
- General Surgery** Operative Clinic
Resection of Lesion of Cardiac End of Stomach. HAROLD LINCOLN THOMPSON.
- Discussion during surgery. EUGENE J. JOHNSON.
- General Surgery** Non operative Clinic
Problems of Anesthesia in Thoracoabdominal Approach to Cardia. End of Stomach. JOHN B. DILLON.
- Fractology** Operative Clinics
Repair of the Incontinent Anal Sphincter. PAUL C. BLAINDELL.
- Anal fissure. PAUL C. BLAINDELL.
- Abdominoperineal Resection—Two-term. MALCOLM R. HILL and ARTHUR TEE.
- Obstetrics and Gynecology** Operative Clinics
Vaginal Hysterectomy. CARL E. KROEMER.
- Discussion during surgery. WILLIAM C. BRADBURY.
- Total Hysterectomy. WILLIAM C. BRADBURY.
- Discussion during surgery. CARL E. KROEMER.
- Orthopedic Surgery** Operative Clinics
Spinal Fusion. JOSEPH CHILDS RUMER.
- Discussion during surgery. G. MONROE TAYLOR.
- Intraosseous fracture. The Newfield Nail. G. MONROE TAYLOR.
- Discussion during surgery. ALONZO J. NEUFELD.
- Orthopedic Surgery** Nonoperative Clinics
Discussion between cases—Anatomical Considerations of the Region of the Hip. CHRISTOPHER MASON, Moderator.
- Problems of Anesthesia. JOHN B. DILLON.
- 9:30 **Tumor Surgery** Nonoperative Clinics
Malignancy Symposium. IAN MACDONALD, Moderator.
- Combined Procedures for Intraoral Cancer. 14th Cervical Metastases. LEWIS W. GUTH, SAMUEL L. PERLITZ.
- Detection and Management of Biologically Inoperable Mammary Carcinoma. LEO M. LEVI.
- Diagnosis and Treatment of Uterine Carcinoma (Cervix, Corpus). JUDITH J. STEIN.

Thursday

- 8:00—9:00. **Obstetrics and Gynecology** Operative Clinics
Suspension of Vaginal Vault from Abdominal Route. HELEN N. SELL.
- Manchester Operation. HAROLD K. MARSHALL.
- Presacral Neurectomy. ERIC HENRIKSEN.
- Gynecological Surgery** Operative Clinics
Nephrectomy (with discussion). JAY J. CRAKE.
- Retroperitoneal Prostatectomy. SAMUEL A. BACON. FREDERICK A. BICKNELL.
- Perineal Prostatectomy. CARL F. RUTCHIE, DONALD A. CHARNOCK.
- Thoracic Surgery** Operative Clinics
Lobectomy. JOSEPH L. ROBINSON.
- Discussion during surgery. JOHN C. JOSEPH.
- Vascular Surgery** Operative Clinics
Thoracolumbar Sympathectomy. RUFERT B. RANNEY.
- GEORGE H. PATTERSON.
- Cervical Disc. AIDAN A. RANNEY. HERBERT G. CHOCKETT.
- Brain Tumor. PHILIP J. VOGEL, FRANK M. ANDERSON.
- Suprarenal Sympathectomy (Pret Operation). EMIL SELTZ, HENRY MICHAEL CUNEO.
- General Surgery** Operative Clinics
Thyroidectomy. CLARENCE E. STAFFORD.
- Discussion of Thyroid Problems. CONRAD J. BAUMGARTNER.

- General Surgery** Nonoperative Clinics
Discussion—Differential Diagnosis of Tumor of the Test (Illustrated—14th charts and models).
- General Surgery** Operative Clinics
Bronchial Plasty. CONRAD J. BAUMGARTNER.
- Discussion of Congenital Lesions of the Neck. CLARENCE E. STAFFORD.
- 9:30. **Orthopedic Surgery** Nonoperative Clinics
Fractures. VICTOR P. THOMPSON, Moderator.
- Fractures and Dislocations of the Hip, Fracture of the Femur. Fracture of the Tibia. SAKETI & MITTAL.
- PAUL E. McMASTER, G. MONROE TAYLOR, ALONZO J. NEUFELD.

Friday

- 8:00—9:00. **Fractology** Operative Clinics
Abdominoperineal Resection. ROBERT L. BELL, JR.
- ELIAM H. DANIEL.
- Flatastomy.
- Hemorrhoidectomy.
- Anal Uter Excision.
- Orthopedic Surgery** Operative Clinics
Amputation. FRANCIS M. McKEEVER.
- Open Reduction Fractured Tibia. P. CH. E. McCLIM.
- Osteotomy of Hip. VICTOR P. THOMPSON.
- Discussion between cases.
- Tumor Surgery** Operative Clinics
Radical Mastectomy. EUGENE J. JOHNSON.
- Discussion of Cancer of Breast. JUDITH J. STEIN.
- Tumor Surgery** Nonoperative Clinics
Biopsy Techniques—Discussion between cases. CLARENCE E. NEILSON.
- Tumor Surgery** Operative Clinics
Radical Neck Dissection. JUDITH J. STEIN.
- Discussion during surgery. CLARENCE E. NEILSON.
- EUGENE J. JOHNSON.
- General Surgery** Nonoperative Clinics
Anatomy of Inguinal and Femoral Regions (Demonstration with charts). COL. LAWRENCE BALL, GORDON K. SMITH.
- General Surgery** Operative Clinics
Surgical Repair of Indirect Inguinal Hernia. COL. LAWRENCE BALL, GORDON K. SMITH.
- General Surgery** Nonoperative Clinics
Survey of Hernia Repair. McCornack General Hospital and Los Angeles County General Hospital from Jan. 1946 to June, 1948 (charts and discussion). COL. LAWRENCE BALL, GORDON K. SMITH.
- General Surgery** Operative Clinics
Surgical Repair of Direct Inguinal Hernia. COL. LAWRENCE BALL, GORDON K. SMITH.
- General Surgery** Nonoperative Clinics
General Discussion of Anesthesia in Elective and Emergency Surgical Procedures for Repair of Hernia. JOHN B. DILLON.
- General Surgery** Operative Clinics
Surgical Repair of Femoral Hernia. COL. LAWRENCE BALL, GORDON K. SMITH.
- General Discussion.
- General Surgery** Operative Clinics
Obstructive Jaundice (Stone Common Duct). JOHN NORTON NICHOLS.
- General Discussion. LEWIS A. ALBERT.
- General Surgery** Nonoperative Clinics
Discussion between cases—The Problem of Disposal of the Acute Abdomen in Children (Illustrated). JOHN NORTON NICHOLS.
- General Surgery** Operative Clinics
Subtotal Gastrectomy Illustrating Use of Alton Tube. LEWIS A. ALBERT.

Discussion during surgery JAMES NORTON NICHOLS.

General Surgery Nonoperative Clinic

Symposium on Fluid, Nitrogen, and Electrolyte Balance

CLARENCE J. BERNZ Moderator

General Review of Current Concepts. JACK M. FAR-
RIS

Discussion of Nitrogen Balance. HARRY A. DAVIS.

Discussion of Acid Base Balance. RALPH E. HOMANN

Presentation of Illustrative Cases. HELEN E. MARTIN

METHODIST HOSPITAL OF SOUTHERN CALIFORNIA, LOS ANGELES

Monday

8:00-12:00 *Thoracic Surgery* Operative Clinic

Selected Cases. LYMAN A. BREWER, FRANK S. DOLLEY

8:00-12:00. *Tumor Surgery* Operative Clinic. Selected

Cases. CLYDE EMERY TUMOR GROUP. SAMUEL L. PERLITZ.

8:00-12:00. *Orthopedic Surgery* Operative Clinic. Selected

Cases. HAROLD E. CROWE, KENNETH TOWNSEND.

8:00-12:00. *Ophthalmology and Otolaryngology* Operative
Clinic: Selected Cases. WALTER R. CRANE.

Friday

8:00-12:00 *Genitourinary Surgery* Operative Clinic

Selected Cases. FREDERICK A. BENNETT, CARL L.
MULFINGER.

8:00-12:00. *Obstetrics and Gynecology* Operative Clinic

Selected Cases. ALEX A. BLATTENWICK, CARL E. KRUG-
MEIER, ELDON W. TICE.

8:00-12:00. *General Surgery* Operative Clinic. Selected

Cases. CLIFFORD O. BISHOP, GEORGE R. DUNLEVY,
LEWIS F. ELLMORE, ADOLPH M. HANSEN, ELMER A.

NELSON, ROY E. SHIPLEY, JOSEPH A. PARKER, HAROLD
P. TUTTIN.

8:00-12:00. *Hand Surgery* Operative Clinic

Selected Cases. JOSEPH H. BOYER.

ORTHOPAEDIC HOSPITAL, LOS ANGELES

Monday

8:00-12:00. *Orthopedic Surgery* Operative Clinic. Spinal

Fusion for Scoliosis. JOSEPH CHARLES RISSE.

Wednesday

8:00-10:00. *Orthopedic Surgery* Operative Clinic. Fascial

Transplants. CHARLES LOWMAN

Thursday Morning

10:00-12:00. *Orthopedic Surgery* Nonoperative Clinic

Surgical Conference. HAROLD E. CROWE.

Every Afternoon

Orthopedic Surgery Nonoperative Clinic.

PHYSICIANS AND SURGEONS HOSPITAL GLENDALE

Days not yet decided

8:30-12:00. *Gynecology* Operative Clinic. Vaginal Plastic

Procedures. HAROLD A. MARSHALL.

8:30-12:00. *General Surgery* Operative Clinic. Two-

Team Abdominoperineal Resection of Rectum. ELMER
BELT.

8:30-12:00. *General Surgery* Operative Clinic. Resection

Carcinoma of Esophagus or Trans thoracic Vagotomy
HAROLD LINCOLN THOMPSON

Orthopedic Surgery Nonoperative Clinic

Knee Surgery. HUGH T. JONES.

Orthopedic Surgery Nonoperative Clinic.

Surgical Treatment of Fractures—motion pictures.

CHARLES W. GILFILLAN

Orthopedic Surgery Nonoperative Clinic

Internal Fixation of Fractures. JOSEPH WOLF

Orthopedic Surgery Nonoperative Clinic

Backache. JOHN R. BLACK.

Gynecology Nonoperative Clinic

General Vaginal Prolapse. HAROLD K. MARSHALL,

DANSON TARR, MATT STURDEVANT

QUEEN OF ANGELS HOSPITAL, LOS ANGELES

Tuesday

8:00-11:00. *Otorhinolaryngology and Ophthalmology* Oper-
ative Clinics

Fenestration Operation. HOWARD P. HOUSE.

Laryngectomy. ALDEN MILLER.

Nasoplasty Operation. JOSEPH GAYNOR.

Strabismus Demonstration of the O'Connor Clinch Oper-
ation and Recession of the Inferior Oblique Muscle.

ALFRED ROBBINS

Cataract Extraction by the Castroviejo Suction Tech-
nique. MAURICE NUGENT

Combined Extraction. STEPHEN POPOVICH

Glaucoma Decompression Operation. IRVING SCHUMAN

10:00-12:00 *Orthopedic Surgery* Operative Clinic:

Symphactectomy for Peripheral Vascular Disease. EDWIN
PLIXTON

11:30-1:00. *Otorhinolaryngology and Ophthalmology* Non-
operative Clinics

Illustrated Lecture on Acute Obstructive Laryngitis.
ALDEN MILLER

Deafness in Children Treated by Radiation. LAWRENCE
GUNDUM

Sclerotic Mastoid and its Roentgen Interpretation.
GILBERT OWEN

The Treatment of Corneal Scars by Beta Irradiation.
WILLIAM H. BOYD

The Tucky Corneal Lens. MAURICE NUGENT

Complication Following Cataract Extractions. IRVING
SCHUMAN

The Scleral Shortening Operation for Detachment of the
Retina. (Motion picture in color) W. E. BOWLEY

Essential Hypertension and its Ophthalmoscopic Inter-
pretations. STEPHEN POPOVICH.

Wednesday

8:00-11:00. *Obstetrics and Gynecology* Operative Clinics

Total Hysterectomy. FRANK F. SCHADE.

Vaginal Hysterectomy. SAMUEL MARTINS

Vaginal Plastic Operation for Correction Cystocele

Rectocele and Laceration of Pelvic Floor. H. NIEBER
GALL.

Vaginal Plastic Operation for Correction of Stress In-
continence of Urine (Kennedy Procedure). DANIEL
MISHELL.

8:00-11:00. *General Surgery* Operative Clinics

Diaphragmatic Hernia Thoracic Approach. J. N.
O'NEILL.

Gall Bladder. ROBERT STEWART

8:00-11:00. *Orthopedic Surgery* Operative Clinics

Hemiated Disc. CHRISTOPHER MASON.

Pinning of Fracture of Neck of Femur. FRED ILFELD.

Arthrotomy for Benign Tumor. JOSEPH PELLIRO.

11:30-1:00. *Obstetrics and Gynecology* Nonoperative
Clinics.

Pregnancy Following Conservative Treatment for Pelvic
Endometriosis. DANIEL MISHELL and UMBERT E.
ANZ.

Early Rupture of the Uterus Before the Onset of Labor
A. M. MCCARTHY and C. V. VON DER AHE.
Low Spinal Anesthesia in Obstetrics. A Report of 2,000
cases. FRANK F. SCHADE and WILLIAM CALDWELL.

Thursday

- 8:00-10:00. *General Surgery* Operative Clinics
Thyroidectomy WALTER SULLIVAN and THOMAS D.
CARLSON.
Radical Mastectomy DONALD E. ROSE.
Abdominal Perineal Resection of Rectum. WILLIAM
DANIEL.
Colon Surgery JAMES L. NEELER and D. A. GAZZARIELLO.
8:00-10:00. *Orthopedic Surgery* Operative Clinics.
Intermedullary Plating of Fracture. Anterior Approach
to Elbow Joint. HOMER PERKINS.
Osteotomy and Fixation of Non-Union of Neck of Femur
by a New Reverse Nail. GALE HUNT.
Subcutaneous Fasciotomy for Dupuytren's Traction.
J. VERNON LOCKE.
10:00-12:00. *Orthopedic Surgery* Nonoperative Clinics.
End Results of Intermedullary Plating of Fracture.
ALFRED GALLANT.
Slipped Upper Femoral Epiphysis. GALE HUNT.
Subcutaneous Fasciotomy (Motion picture) J. VERNON
LOCKE.
Reconstruction of Elbow J. Juries. HOMER PERKINS.

Friday

- 8:00-10:00. *General Surgery* Operative Clinics.
Tractotomy for Tic Douloureux. RUPERT B. RANNEY.
Gall Bladder Surgery WALTER HOLLERMAN.
Carcinoma of Bladder. FRED BICKNETT.
Partial Gastrectomy JAMES F. REGAN.
Resection Carcinoma of Esophagus. FRANK S. DOLLEY
and LYMAN BREWER.
Retropubic Prostatectomy MORTON M. MAYERS.
Thyroidectomy DANIEL FORTMAN.
10:00-12:00. *General Surgery* Nonoperative Clinics.
Radical Mastectomy (Motion picture in sound and
color) DONALD E. ROSE.
Mastopexy (Motion picture in color) JOSEPH GAYNOR.
Sympathectomy (Motion picture) RUPERT B. RANNEY.
Diabetes Mellitus Complicating Surgery. KENNEDY
SMITH.

ST. JOHN'S HOSPITAL, SANTA MONICA

Monday

- 8:00-10:00. *General Surgery* Operative Clinics: Surgery of
the Gallbladder. RODRICK M. NEALE.
8:00-10:00. *Obstetrics and Gynecology* Operative Clinics:
Cesarean Section (Bicornuate Uterus). B. H. W. THOM.
10:00-12:00. *General Surgery* Operative Clinics: Surgery
of the Colon. G. ARNOLD STEVENS.
1:00-3:00. *Orthopedic Surgery* Operative Clinics: Limb-
ectomy with Spinal Fusion. DANIEL H. LEVINTHAL.

Tuesday

- 8:00-10:00. *General Surgery* Operative Clinics: Thyroid-
ectomy. G. ARNOLD STEVENS.
8:00-10:00. *Obstetrics and Gynecology* Operative Clinics:
Anterior and Posterior Colpoperineoplasty and Kelly
Stitch. JAMES C. DOTY and ALBERTUS C. MERTUS.
10:00-12:00. *General Surgery* Operative Clinics: Gastric
Resection. MARCUS H. RABWIN and DAVID H. ROSEN-
BLUM.
10:00-12:00. *Orthopedic Surgery* Operative Clinics: Ar-
throscopy of the Knee. DANIEL H. LEVINTHAL.

Wednesday

- 8:00-10:00. *General Surgery* Operative Clinics: Radical
Mastectomy. JOHN F. ROBERTS.
8:00-10:00. *Gastroenterology* Surgery Operative Clinics:
Retro-public Prostatectomy. GILBERT J. THOMAS and
FRED C. SCHLUMBERGER.
10:00-12:00. *General Surgery* Operative Clinics: Vaginal
and Posterior Gastroenterostomy. FRANK I.
BROWNE and HENRY J. LANGE.
10:00-12:00. *Plastic Surgery* Operative Clinics: Re-
plasty. J. J. FREEMAN.

Thursday

- 8:00-10:00. *General Surgery* Operative Clinics: Hemo-
rhaphy (Tantalum Gauze and Tantalum Wire).
MARCUS H. RABWIN and DAVID H. ROSENBLUM.
8:00-10:00. *Obstetrics and Gynecology* Operative Clinics:
Total Hysterectomy. B. H. WATSON.
10:00-12:00. *General Surgery* Operative Clinics: Vaginal
Hemorrhaphy. FRANK E. BROWN and HENRY
J. LANGE.
10:00-12:00. *General Surgery* Operative Clinics: Ex-
cision of Common Duct. G. ARNOLD STEVENS.

Daily. Pathological, nonoperative clinic, Rapid Method of
Surgical Tissue Diagnosis. G. H. HUNTER.
Daily. Micro. Laboratory, nonoperative clinic, Photo-
graphic Aids. G. H. HUNTER.

ST. JOSEPH HOSPITAL, BURBANK

Days not yet decided

General Surgery Operative Clinics: Selected cases

ST. LUKE HOSPITAL, PASADENA

Day not yet decided

Orthopedic Surgery Nonoperative Clinics.
Gastroenterology Surgery Nonoperative Clinics.

ST. VINCENT'S HOSPITAL, LOS ANGELES

Tuesday

- 9:00-10:00. *Otolaryngology* Operative Clinics: Scleral
cases. J. MACKENNIE BROWN.
9:00-10:00. *Ophthalmology* Operative Clinics: Scleral
cases. A. RAY IRTVING.
9:00-10:00. *General Surgery* Operative Clinics: Thyroid-
ectomy. WILLIAM P. KROGER.
9:00-10:00. *General Surgery* Operative Clinics: Scleral
cases. FRANK J. BRIDLIN.
9:00-10:00. *General Surgery* Operative Clinics: Scleral
cases. FRANCIS E. BROWNE, HENRY J. LANGE.
9:00-10:00. *Tumor Surgery* Operative Clinics: Scleral
cases. IAN MACDONALD, LEWIS W. GORD.
10:00-12:00. *Tumor Surgery* Nonoperative Clinics: Li-
gament Lesions of Colon. KENNEDY S. DAVIS.
1:30-3:00. *General Surgery* Nonoperative Clinics: Sur-
gery of Colon—motion picture. WILLIAM H. BURNETT.
10:00-12:00. *General Surgery* Nonoperative Clinics: Sur-
gery of Esophagus—motion picture. HAROLD LINDEN-
THORNTON.
11:00-12:00. *General Surgery* Operative Clinics: Scleral
cases. CONRAD J. BAUMGARDNER.
1:00-2:00. *General Surgery* Operative Clinics: Colon
Surgery. RALPH V. BYRDE.

Wednesday

- 9:00-12:00. *Orthopedic Surgery* Operative Clinics: Scleral
cases. FLORENCE T. JONES, JOHN R. BLACK.

- 9:00-12:00. *Orthopedic Surgery* Operative Clinic Selected cases. FRANCIS A. McKEEVER
- 9:00-12:00. *Neurosurgery* Operative Clinic Selected cases. RUPERT B. RAMEY
- 9:00-12:00. *Neurosurgery* Operative Clinic Selected cases. C. HUNTER SHILKIN
- 9:00-12:00. *Otolaryngology* Operative Clinic Fenestration. HOWARD P. HOUSE
- 9:00-12:00. *Ophthalmology* Operative Clinic Selected cases. JOHN P. LORDAN
- 9:00-12:00. *Plastic Surgery* Operative Clinic: Selected cases. ARTHUR E. SMITH
- 10:00-
10:30-
11:00-
Tumor Surgery Nonoperative Clinic Thyroid Malignancy. HENRY J. LANGE
Tumor Surgery Nonoperative Clinic Struma Lymphomatosa and Fibrosis. ROBERT C. SURRIDGE
General Surgery Nonoperative Clinic Obstructive Corrosive Gastritis. LOUIS C. BENNETT

Thursday

- 9:00-11:00. *General Surgery* Operative Clinic: Selected cases. E. VINCENT ARNEY
- 9:00-
Otolaryngology Operative Clinic: Selected cases. JOSEPH H. STEVENS
- 9:00-12:00. *Gynecology* Operative Clinic Selected cases. BERNARD J. HANLEY JOHN C. McDERMOTT
- 9:00-12:00. *Proctology* Operative Clinic Surgery of Colon. WILLIAM H. DANIEL
- 9:00-12:00. *General Surgery* Operative Clinic Vagus Neurectomy. EDWARD C. PALLETTE
- 9:00-12:00. *Ophthalmology* Operative Clinic: Selected cases. CLARENCE H. ALBAUGH
- 10:00-
10:30-
11:00-
Surgery of Hand. FRANK J. BRISLIN
Orthopedic Surgery Nonoperative Clinic
Surgery of Knee Joint. HUGH T. JONES, JOHN R. BLACK
Neurosurgery Nonoperative Clinic: Surgical Management of Intracranial Aneurysms—motion picture and lantern slide illustrations.
- 11:00-12:00. *General Surgery* Operative Clinic: Selected cases. E. ERIC LARSON

Friday

- 9:00-11:00. *General Surgery* Operative Clinic: Selected cases. LOUIS C. BENNETT
- 9:00-12:00. *Plastic Surgery* Operative Clinic Selected cases. ARTHUR E. SMITH
- 9:00-12:00. *General Surgery* Operative Clinic: Selected cases. FRANCIS E. BROWNE, HENRY J. LANGE
- 9:00-12:00. *General Surgery* Operative Clinic. Selected cases. WILLIAM P. KROGER, ROBERT C. SURRIDGE
- 9:00-12:00. *Genitourinary Surgery* Operative Clinic Selected cases. ALBERT J. SCHOLL, EDMUND CROWLEY
- 10:00-
10:30-
11:00-
General Surgery Nonoperative Clinic Trans-thoracic Vagus Neurectomy. E. C. PALLETTE
General Surgery Nonoperative Clinic Surgery of Spleen. RALPH V. BYRNE
General Surgery Nonoperative Clinic Carcinoma of Tongue, or Primary Mandibular Tumors. IAN MACDONALD, LEWIS W. GILES
- 11:00-12:00. *General Surgery* Operative Clinic Selected cases. DAVID A. SCHMIDT

SANTA FE COAST LINES HOSPITAL,
LOS ANGELES

Monday

- 9:00-11:00. *Genitourinary Surgery* Operative Clinic Retroperitoneal Prostatectomy. V. J. GALLAGHER

- 9:00-10:00. *Neurosurgery* Nonoperative Clinic The Herniated Intervertebral Disc, Discussion of Multiple Herniations. HENRY M. CUNEO
- 9:00-10:00. *Otolaryngology* Nonoperative Clinic Allergy of the Nose and Paranasal Sinuses. GORDON J. MCCURDY

THE SANTA MONICA HOSPITAL

Thursday

- 9:00-11:00. *General Surgery* Nonoperative Clinics Traumatic Surgery. CHARLES A. LINQUIST
A New Method for the Movement of Fluids in the Extremities. J. P. SAMPSON and FREDERICK G. KIRBY
- Orthopedic Surgery* Operative Clinic Reconstruction of Orthoplasty of Congenitally Dislocated Hip. WILLIAM H. WRIGHT
Demonstration Pre-ambulatory Diagram of Dislocated Hips. JOSEPH C. RISSER
Contrast Orthogram of Dislocated Hips. RALPH MILLER

U. S. ARMY McCORMACK GENERAL
HOSPITAL, PASADENA

Friday

- 9:00-9:30. *Genitourinary Surgery* Nonoperative Clinic Amicrobic Urinary Infections. LYMAN STEWART
- 9:30-10:00. *General Surgery* Nonoperative Clinic The Treatment of Regional Ileitis. GORDON E. SMITH
- 10:00-10:30. *Plastic Surgery* Nonoperative Clinic Treatment of Facial Injuries. MONROE K. ROCH
- 10:30-11:00. *Orthopedic Surgery* Nonoperative Clinic Treatment of Fracture of Forearm. VERNON J. LUCK
- 11:00-11:30. *General Surgery* Nonoperative Clinic Hernia Repair Using Cooper's Ligament. LAWRENCE C. BALL

U. S. NAVAL HOSPITAL, LONG BEACH

Day not yet decided

- 9:00-12:00. *General Surgery* Operative Clinics. Gastroenterology. E. ERIC LARSON Cholecystectomy. L. L. BEAN
- 9:00-12:00. *Genitourinary Surgery* Operative Clinics Retro Public Prostatectomy. CARL F. RUSCHKE
Varicocelectomy. MILLO ELLIS and L. A. NEWTON
- 9:00-12:00. *Orthopedic Surgery* Operative Clinic Operation for Recurrent Dislocation of the Shoulder. R. R. MYERS and JOHN M. ROWE
- 9:00-12:00. *Otolaryngology* Operative Clinic Rhinoplasty Using Cancellous Bone. E. KING, ROBERT C. BOYDEN F. L. ASHLEY
- 9:00-12:00. *Neurosurgery* Nonoperative Clinic Cerebral Aneurysm. ROBERT H. PUDENZ, CHAS. H. SHIELDS, ARTHUR L. SCHULTZ
- 9:00-12:00. *Thoracic Surgery* Nonoperative Clinic Carcinoma of the Lung. BERT H. COTTON and V. C. STRATTON
- 12:00-1:00. *General Surgery* Nonoperative Clinics Ward Rounds, Follow up on Vagus Resection and Gastric Resection. E. ERIC LARSON, RALPH V. BYRNE, WILLIAM E. DELIVERY, CALVIN A. LAUER, L. L. BEAN
- 1:00-4:00. *Genitourinary Surgery* Nonoperative Clinic Post-operative Results from High Varicocelectomy. CARL F. RUSCHKE, MILLO ELLIS, and L. A. NEWTON
- 4:00-4:30. *Otolaryngology* Nonoperative Clinic Motion Pictures. Nasal Bone Graft and Post-operative Results. E. KING, ROBERT C. BOYDEN, KENNETH C. BRANDENBERG
- 12:00-1:00. *Neurosurgery* Operative Clinic Trans-frontal Craniotomy or Cervical Disc. C. HUNTER SHIELDS, ROBERT H. PUDENZ, ARTHUR L. SCHULTZ

100-400. *Thoracic Surgery* Operative Clinic:
Pneumonectomy. **BERT H. COTTON** and **V. C. STRATTON**
100-400. *Orthopedic Surgery* Nonoperative Clinic:
Ward Rounds, Post Operative Care of the Orthopedic
Patient. **JOHN M. ROWE** and **R. R. MYERS.** J. G.
MARKING.

U. S. VETERANS ADMINISTRATION
BIRMINGHAM GENERAL HOSPITAL, VAN NUYS

Wednesday

9:00-10:00. *Genitourinary Surgery* Nonoperative Clinics
Results of Uretero-Intestinal Implantation and Cystec-
tomy for Carcinoma of Bladder. **DOMALD C. MAL-
COLM.**

Thoracic Surgery Operative Clinic.
Pulmonary Decortication. **JOSEPH A. WIEDERHOLZ.**

General Surgery Operative Clinics
Surgical Problems of the Paraplegic. **ERNEST BOSS.**
Trans Abdominal V.otomy and Gastrojejunostomy
FRANKLIN B. WILKINSON.

Thoracolumbar Sympathectomy by Intercostal Ap-
proach. **THEODORE B. MARSHALL.**

Neurosurgery Operative Clinic Cervical Laminectomy for
Disogenic Disease. **JOHN D. FRIEDMAN.**

Otorhinolaryngology Operative Clinics Reconstructive Rhin-
oplasty for Nasal Obstruction. **SAMUEL KAPLAN.**

Endaural Radical Mastoidectomy. **SAMUEL KAPLAN.**
100-400. *Orthopedic Surgery* Nonoperative Clinics
Care of Traumatic Injuries of the Hand. **JOHN H. ALDER**
and **JOSEPH H. BOYES.**
Treatment of Bone and Joint T.B. with Streptomycin.
JOHN H. ALDER.

U. S. VETERANS ADMINISTRATION CENTER,
WADSWORTH GENERAL HOSPITAL, SAWTELLE

9:00-10:00. *General Surgery* Nonoperative Clinics
Symposia. Tri-ethyl ammonium in Evaluation of
Peripheral Vascular Disease. **C. H. MCINTYRE.**
Results of Histidine and Ascorbic Acid Treatment of
Peripheral Vascular Disease. **RODOLPH WITTMANN** and
MILTO REYNOLDS.

A New Method for the Movement of Fluids in the Ex-
tremities. **F. G. KIRBY** and **J. P. SAMPSON** (Santa
Monica Hospital).

Orthopedic Surgery Nonoperative Clinic
Symposium Amputations in Peripheral Vascular Dis-
ease. **ROBERT MAZET.**

General Surgery Operative Clinic:
Lumbar Sympathectomy. **CHARLES S. KOTZ.**
Anesthesia Operative Clinic: Pain Clinic. **CARLES J.**
MCCURRY, **LEONARD W. ARNOCK**, and **NATHAN B. RO-**
Ophthalmology and Otorhinolaryngology Nonoperative
9:00-9:30. Fundus Lesions with Pathological Section and
Microphotographic Slides. **A. RAY LUTHER** and **CARLES**
S. KOTZ.

9:30-10:00. Malignancies of Ear, Nose and Throat and
Case Presentations. **CLAUDE S. MICHON** and **STAFF.**

10:00-10:30. Frenotomy Operation for Oromaxillary and
Case Presentations. **CLAUDE S. MICHON** and **STAFF.**

WHITE MEMORIAL HOSPITAL, LOS ANGELES

Thursday

9:00-10:00. *Genitourinary Surgery* Operative Clinic:
Vesical Diverticulectomy and Urethroplasty for Urinary
Incontinence. **ROBERT W. BARNES**, **R. THOMAS**
BERGMAN.

9:00-10:00. *Orthopedic Surgery* Operative Clinic:
Surgical Treatment of Corns, Metatarsal Callus,
Hammer Toe, and Bunions. **ALONZO J. VERNER** and
ASSOCIATES.

10:00-11:00. *Genitourinary Surgery* Operative Clinic:
Transurethral Prostatic Resections. **ROBERT W. BARNES**,
R. THOMAS BERGMAN.

11:00-12:00. *Genitourinary Surgery* Nonoperative Clinics
Motion Picture Film—Transurethral Prostatic Resec-
tion. Lantern Slide Demonstration. Round table Dis-
cussion. **ROBERT W. BARNES**, Moderator.

Wednesday

9:00-10:00. *General Surgery* Operative Clinic:
Total Excision of Parotid Gland with Preservation of
Facial Nerve. **CHARLES E. NELSON** and **STAFF.**

Obstetrics and Gynecology Operative Clinics:
Vaginal Hysterectomy—Low Cervical Cesarean Section.
RALPH J. THOMPSON and **STAFF.**

Thursday

9:00-10:00. *Proctology* Operative Clinics:
Two-team Abdominal Perineal Resection for Carcinoma
of the Rectum, Ano-rectal Surgery (Sectored Anal).
MALCOLM R. HILL and **ASSOCIATES.**

Otolaryngology Operative Clinics:
Frenotomy Rhinoplasty—Endoscopic Clinic. **BROWN**
N. COLVER and **ASSOCIATES.**

COLLECTIVE REVIEW

THE EARLY TREATMENT, AND RESULTS THEREOF, OF INJURIES OF THE COLON AND RECTUM¹

With 70 Additional Cases

EDMUND R. TAYLOR, M.D., Chapel Hill North Carolina and JAMES E. THOMPSON M.D.,
New York, New York

OPERATIVE TREATMENT OF WOUNDS OF THE RECTUM

It is in the treatment of rectal wounds that the greatest reduction in the mortality rate of wounds of the large intestine has occurred. In World War I the mortality rate was very high and wounds of the rectum were more grave than those of the colon. Today the reverse is true. In World War I the method of treatment was not the same as that of today. Proximal colostomy was used only in severe wounds. Most men did not recognize the value of wide drainage in extraperitoneal wounds. However some men clearly realized the great importance of wide retrorectal drainage and carried it out in their cases. Drummond and many others recognized that retroperitoneal infection was a very serious threat in these cases.

Intraperitoneal wounds of the rectum. With regard to these types of wounds, Drummond wrote

"Intraperitoneal wounds of the rectum low down in the retrovesical pouch are most difficult to treat by suture on account of the depth of the narrow male pelvis, and I think in these cases Sir Cuthbert Wallace's suggested obliteration of the retrovesical pouch by sutures with the addition of a colostomy, a plan well worth a trial or the introduction of a large tube into the anus to provide for very ample drainage. Again these intraperitoneal rectal wounds are frequently accompanied by much laceration of the lowest coils of the ileum

as it lies in the true pelvis and also by injury of the bladder and severe compound fracture of the pelvic bones. In six of the sixteen cases in this series the small bowel was perforated, and the bladder ruptured four times whilst the sacrum and pelvic bones were fractured in eight cases.

In extraperitoneal wounds of the rectum the only hope of success lies in very free local drainage carried out at the earliest possible moment. With a view to establishing efficient drainage I removed in two cases the uninjured coccyx in addition to free drainage of the wounds of entry and exit, and found by stripping up the bowel that one was able to expose the wound in the rectum and was thus enabled to drain and pack off the surrounding parts and prevent further tracking by retroperitoneal hemorrhage. Both patients succumbed from other complicating wounds, but I think in suitable cases the plan is a good one.

From a review of his reports of cases it was strikingly the complete inadequacy of his supportive treatment that caused his failures. He did not transfuse blood or employ chemotherapy. By the end of the war proximal colostomy and retrorectal drainage had already assumed an important place in the treatment of rectal wounds. The results obtained in two other series are interesting. Wallace and Bowley in a series of 965 cases of abdominal wounds treated surgically had 21 patients with rectal wounds, with a mortality rate of 66 per cent. In their treatment drainage

¹Continued from August issue.

TABLE XIII.—INTRAPERITONEAL WOUNDS OF THE RECTUM MORTALITY RATES AS REPORTED IN WORLD WAR II SERIES

Series	Patients		Mortality per cent
	No.	Deaths	
Morgan	5		40.0
Pearson and associates	8	1	12.5
Present series	6	4	66.7
Totals	9	5	55.6

wound or by making the wound extraperitoneal, with the use of generous drainage and defunctionalization of the wounded segment.

Extraperitoneal wounds of the rectum More has been written about extraperitoneal wounds of the rectum. It is in these wounds that primary treatment is most satisfactory. The mortality rate associated with such wounds is now the lowest of any wounds in any part of the large intestine about 6 per cent when proper treatment is carried out. In World War I these wounds were virtually lethal. The modern operative treatment of such wounds, the rationale of the different steps in the operative approach and the results thereof will be considered next.

The two most fundamental steps are performance of proximal colostomy and the establishment of drainage of the retrorectal spaces. The results obtained when these two steps have been used routinely are shown in Table XIV which is adapted from reports of American surgeons in Europe. These results are contrasted with results in Morgan's British series which he composed from data also from the European Theater.

Other British series in the literature are not broken up into intraperitoneal and extraperitoneal wounds. Ogilvie (18) cited 47 cases of rectal wounds in Africa in which the mortality rate was 36.1 per cent. From the Twenty First Army Group in Europe Porritt cited 39 cases of rectal injury alone, with a mortality rate of 36 per cent, and 70 cases of rectal injury combined with injury to other abdominal organs, with a mortality rate of 50 per cent. In Ogilvie's and Porritt's series no detailed analysis of treatment was given. Ogilvie's policy was one of performance of colostomy for even suspected wounds of the rectum in all cases but routine institution of retrorectal drainage in extraperitoneal wounds was not so strongly emphasized as in the American armies of the European Theater of Operations. Porritt did not describe the policies carried out in the Twenty First Army Group.

TABLE XIV.—EXTRAPERITONEAL WOUNDS OF THE RECTUM MORTALITY RATE WITH AND WITHOUT ROUTINE USE OF COLOSTOMY AND RETRORECTAL DRAINAGE

Series	Patients	Deaths	Mortality Per cent
Colostomy and retrorectal drainage used routinely			
Jarvis, Byers, Platt	9	0*	0*
Bradford, Battle, Paschhoff	18		3.6
Leefman	23	2	8.6
Hart	6		
Pearson, Tuby and Welch	35		6
Present series	7		14.3
Totals	120	2	1.7
Colostomy and retrorectal drainage not used routinely			
Morgan	20	0	0.0

*This information received by personal communication.

In extraperitoneal wounds the excellent results procured by the routine use of colostomy and wide retrorectal drainage speak for the fundamental soundness of this method of treatment. The poorer results in Morgan's cases and in Ogilvie's, in which these methods were not so routinely used, suggest that it is unsound to compromise either of these two principles. Morgan analyzed his cases in which death ensued, and it is clear that when either colostomy or retrorectal drainage was not used or was attempted late the result was severe infection. Six of the 8 deaths in his series were caused by severe sepsis. Croce, Johnson and Wiper gave definitive treatment and observed this type of condition late. They came to the conclusion that both colostomy and retrorectal drainage are necessary to prevent sepsis and to obtain healing of the rectal wounds. Thus, we consider it conclusively proved that colostomy combined with wide retrorectal drainage gives excellent results, and that to omit either one is to court disaster.

Pelvic infection is the danger when either colostomy or wide drainage is omitted. This infection was clearly recognized in World War I. Drummond described it as being a most severe and often fatal infection. It is now recognized as the most serious complication of the extraperitoneal rectal wound. It can develop early and can be fulminating with death resulting within 24 hours, or it can develop late. Once the infection has taken a firm hold, it is apparently difficult to drain the process. The patient might die of chronic suppuration weeks after he had been wounded.

was not mentioned. These authors advised proximal colostomy only in the presence of very severe wounds of the rectum and when the suture line was thought to be poor. Fraser and Drummond reported 10 cases of rectal wounds in which the patients were treated surgically and the mortality rate was 70 per cent. In their series of extraperitoneal wounds the entrance wound was opened thoroughly and proximal colostomy was reserved for severe wounds. Intraperitoneal wounds were sutured only. It must be remembered that in World War I after the policy to operate on abdominal wounds was accepted, many surgeons operated alone, none had chemotherapy or the transfusion of blood available to them, and the value of gastric suction was not recognized. Many patients came in and were not operated upon because they were considered moribund.

The attitude of the United States Army at the end of World War I is summed up in the following, quoted from Lee in *The Medical Department of the United States Army in the World War*:

"The extraperitoneal injuries are best treated by careful debridement of the buttock or perineal wound, the dissection being carried upward and into the rectum. It may be necessary to open widely the lower segment of the bowel in order that complete dissection of the tract may be accomplished and that adequate drainage may be most effectively placed in the retroperitoneal tissues. Extensive lacerations of the lower segment may require a colostomy. Intraperitoneal injuries are treated by a median laparotomy with suture of the opening wherever it is possible to accomplish it. Drainage through the lower angle of the operative wound should always be practiced, rubber dam being the best material for the purpose. If a suture cannot be made, owing to the depth of the rectal wound in the pelvis, a colostomy should be performed.

"The mortality with wounds of the rectum is 45 to 50 per cent. Usually death is due to a rapidly advancing sepsis in the retroperitoneal tissues or to a severe spreading peritonitis."

In World War II the mortality rate associated with rectal wounds probably was reduced more dramatically than were mortality rates accompanying wounds of any other abdominal viscus. Whole blood and plasma became available, and usually were used most liberally by the Americans and British. Likewise, the sulfonamides, penicillin, or both were available in most cases. These adjuncts to treatment were of tremendous value, and enabled surgeons in this war to undertake and complete successfully operations which undoubtedly would have been failures in the earlier war.

We are convinced that a change in the operative treatment also was very important in the reduction of this particular mortality rate.

The change in the operative treatment of intraperitoneal wounds consisted of the change from only rare performance of proximal colostomy to routine use of it. Ogilvie (28) stressed the importance of proximal colostomy in all rectal wounds. It is difficult to determine how greatly this change in procedure influenced the mortality rate. In most series the mortality rates associated with extraperitoneal and intraperitoneal wounds of the rectum are not presented separately so that the respective mortality rates for each type of wound are not given. It can be said only that the mortality rate accompanying rectal wounds in general has been greatly reduced.

A few surgeons have, however, reported mortality rates associated with intraperitoneal wounds of the rectum as shown in Table XIII. On the basis of the small group of cases in this table, it appears that in intraperitoneal wounds the outlook is much poorer than in extraperitoneal wounds, in which the mortality rate is around 6 per cent, as will be shown later herein. This higher mortality rate associated with intraperitoneal wounds probably is due to the shock associated with fecal contamination of the peritoneal cavity. Probably also, in intraperitoneal wounds there are more associated intra abdominal injuries such as damage to the small intestine and bladder.

In our 6 cases of intraperitoneal wounds of the rectum, multiple organs were injured in 4. All 4 patients died. In contrast, of our 17 patients with extraperitoneal rectal injuries only 5 had injury of multiple organs. Pearson and his associates had 8 patients with intraperitoneal rectal injury. Of these 8 patients, 3 had injury of multiple organs and 1 died; all 5 with no other organ injured lived.

Occasionally there occurs in these wounds the difficult situation in which it is not possible to close the rectal wound. Morgan cited 3 such cases; both patients died. We had no such patients. It would seem that every effort should be made to close off the open rectum from the peritoneal cavity. Wallace suggested obliteration of the rectovesical pouch with sutures in wounds situated very low. The pelvic peritoneum might be mobilized and sutured above the wound, so that the wound becomes extraperitoneal. If this were done, establishment of wide drainage from below would be compulsory. Moreover the pelvis should be drained through the anterior abdominal wall. Thus, we think such desperate situations should be handled along the general lines of closure of the

are passed up to or above the level of the perforation.

Bradford, Battie and Pasachoff had 28 cases of wounds of the extraperitoneal portion of the rectum with 1 death. They said:

In extraperitoneal rectal wounds adequate drainage is most important and this may necessitate removal of the coccyx. Drainage through the gluteal muscles should be avoided where possible. In all rectal wounds whether intraperitoneal or extraperitoneal a proximal colostomy should be performed to prevent further soiling and to allow for healing of the injured part.

Laufman in 35 consecutive cases of battle injuries to the extraperitoneal part of the rectum, had 3 deaths, only 1 of which was due to the rectal wound. Except for the injuries of one patient first seen 6 days after wounding and in excellent condition these wounds were treated by colostomy complete débridement of the tract and adequate incision of the rectal portion of the endopelvic fascia (fascia propria) with suture of the rectal wall when the defect was large. Coccygectomy was reserved for the most part for those patients who had a damaged coccyx.

We had 17 patients with extraperitoneal wounds of the rectum one of them died. The condition of the patient we lost was so poor that all we could do was to perform proximal colostomy and establish some degree of drainage from the rectal wound to the outside. We were unable to do any débridement of multiple fractures the patient later died of gas gangrene in these wounds.

We treated our patients by proximal colostomy and wide drainage of the rectal wound and the retrorectal tissue spaces never omitting either step. If adequate exposure or drainage was interfered with by the coccyx, we performed coccygectomy. In some cases the wound in the rectum was sutured in others, it was left open.

The site of colostomy should be in the left inguinal region and the sigmoid colon should be utilized. If there is severe damage of the rectum and if the sigmoid colon might be needed later on for repair or reconstruction of the rectum, the transverse colon should be utilized for colostomy. The same is true if there is much swelling of the mesosigmoid from gas or hemorrhage which might threaten obstruction or impairment of the blood supply. If the colon has been exteriorized proximal to the rectum for a more proximal wound in the colon this one colostomy is sufficient so long as the fecal stream is diverted from the rectum. Hurt declared

Communication with surgeons in Base Hospitals has revealed that loop colostomy for rectal

injuries has failed in many instances to completely divert the fecal current. Consequently, patients with rectal injuries have arrived with fecally contaminated buttock wounds, and the rectum filled with feces.

The loop probably should be completely divided for rectal wounds of severity when complete diversion of the fecal current from the rectal wound is particularly wanted. The complete division of the distal segment better than does the partially divided loop.

Coccygectomy is certainly not necessary in all cases. We and many others have drained extraperitoneal wounds successfully without it. The indications for its use in the early treatment of rectal wounds are not clear to us as yet. We did not have the opportunity of following our patients long enough to determine whether or not complications arose by our not using it. We did coccygectomy in 5 of our 17 cases of extraperitoneal rectal wounds. Coccygectomy was employed when ever exposure was interfered with by the coccyx in the establishment of drainage or when the coccyx was injured. Our drainage probably was inadequate in one case in which we received a report that coccygectomy had been performed at a hospital in the rear. From those who carried out definitive treatment probably will come the answer as to when coccygectomy is necessary. There is little written about it. Hurt wrote Colcock has reported that osteomyelitis of the sacrum has been a frequent complication of coccygectomy in those with rectal wounds. Croce and associates, who carried out definitive treatment, think coccygectomy should be used in all wounds of the extraperitoneal portion of the rectum. Roettig, Glasser and Barney rendered definitive treatment to 9 patients with rectal wounds produced by missiles perforating the sacrum or sacrum and coccyx. Osteomyelitis developed in most of these patients and was a problem. Excision of the coccyx by Roettig and associates was an important step in the surgical treatment of these patients in order to obtain exposure of the rectum. These cases of Roettig and associates bring up the question of closure of the rectal perforation.

All writers agree that intraperitoneal rectal wounds should be closed in all cases when this is possible. However concerning the closure of extraperitoneal wounds, there is still disagreement. In regard to extraperitoneal wounds, Jarvis and associates wrote: No attempt has been made to suture lacerations of the rectum since early experience demonstrated that these suture lines do not hold. In fact, additional rectal wall may be sacrificed by its inclusion in the suture. Adequate

An example of such an infection is summarized below with a description of the important anatomic points with which we are concerned in extraperitoneal rectal wounds.

The rectum, the terminus of the large bowel, is arbitrarily said to begin at the level of the third sacral vertebra and end in the anal canal. Its average length is 25 cm. The lateral and anterior surfaces of the proximal portion, 5 cm. in the male, 7 cm. in the female, are invested with peritoneum. The posterior surface of this proximal portion is retroperitoneal, the distal portion is intraperitoneal. The rectum ending below at the level of the internal sphincter to become the anal canal is approximately 10 cm. long and is circumscribed by the external sphincter. The internal structure of the pelvic floor through which the rectum passes, may be likened to a trough, the sides of which are formed by the levator ani and coccygeal fat, elongate muscles originating from the internal surfaces of the pelvis on either side, from the pubic tubercle in front to the coccyx behind, to join in a median raphe below. The triangular anterior wall is formed by the urogenital triangle, but the triangular posterior wall is formed by the sacrum and coccyx. Through this troughlike space descend the rectum posteriorly and the urogenital tract anteriorly. Over this troughlike space and its sacra the peritoneum is loosely draped as a cover. Actually, this space is more potential than real, since it is filled with cellular areolar tissue. This space is, therefore, bounded laterally by the levators, inferiorly by their raphe, anteriorly by the urogenital triangle posteriorly by the sacrum and coccyx, and superiorly by the peritoneum, and will be referred to as the infraperitoneal space. When this space is distended by pus or blood, its expansion is found to be definitely limited in certain directions, relatively unlimited in others. Rigid fascial planes prevent extension in any direction except superiorly. Laterally these fascial planes are formed by the medial investment of the levators, the superior levator fasciae. These layers join inferiorly over the raphe and become continuous at the rectal and urogenital outlet with similar layers of fascia loosely investing these ischa, the endopelvic fascia. Anteriorly the superior levator fasciae fuses with the deep layers of the urogenital triangle and posteriorly with the perineal layer of the sacrococcygeal fascia. Expansion of the infraperitoneal space is, therefore, limited inferiorly laterally anteriorly and posteriorly by fascial planes, but is relatively unimpeded superiorly by the loose peritoneal roof. Even thus, however, it is rather firmly directed laterally along the line of origin of the levators, the so-called "linea lineae" here levator fasciae fuses with the levator fasciae above. Since the peritoneum is most loosely attached over the sacral promontory on either side of the rectum, it is here that the infraperitoneal space readily communicates with the retroperitoneal space. When the infraperitoneal space becomes distended with pus or blood, it, therefore, spills through this escape route into the retroperitoneal space. This has been demonstrated experimentally in the cadaver by the serial roentgenologic studies of progressive injection of sodium iodide solution into the infraperitoneal space. It is also well illustrated in one of the cases presented below. [The case they presented in a soldier with an extraperitoneal wound which was not recognized early and in which drainage or colostomy was not employed until weeks after he had been wounded. He died about 4 months after wounding, of hemorrhage.] A topos revealed marked caecocolic. The peritoneal floor of the pelvis externally had been raised by the underlying necrotizing infection of the infraperitoneal space. This infection was not only posterior about the rectum, but had extended anteriorly about

the bladder. It communicated with the abscess underlying the left gluteal muscles through the bullet tract in the left levator muscle. There was perforation of the rectum in its posterior wall about 5 cm. above the anal orifice. The bullet lay imbedded in a crumbled mass of cancellous bone of the first and second sacral vertebrae near the sacro-lumbar joint just above the peritoneal reflection. Therefore, the fecal bacilli had extended retroperitoneally to the right iliac fossa where it continued to burrow upward along the posterolateral wall of the ascending colon almost to the liver. About midway in the ascending colon, secondary ileocolic communication had become established with the retroperitoneal space (?).

The detailed treatment as carried out by different men will be presented. It is to the British that we owe this fundamental contribution to rectal surgery. As we have shown it was they in World War I who were stressing the importance of colostomy and drainage. It was the British in Africa under Ogilvie's direction who stressed colostomy and drainage, and showed the excellent results achieved by their use.

Ogilvie (28) stated: "All injuries of the rectum, however trivial, require a proximal colostomy. In most extraperitoneal injuries the retroperitoneal space should be drained either through the posterior wound or in the midline after the coccyx is removed. The anal sphincter must never be divided, but a large tube should be stitched into the anus."

Hurt wrote:

"The initial surgery of extraperitoneal perforations of the rectum consisted of thorough débridement of the wound tract, suture of perforations, and sigmoid colostomy. In addition, resection of the coccyx and incision of the fascia propria were done to insure adequate drainage of the retroperitoneal, posterior and pararectal spaces. All sigmoid colostomies were of the loop type. It is the feeling of most of our surgeons that adequate drainage can be ensured through a curved incision inferior to the coccyx. Incision of the fascia propria and opening of the posterior and pararectal spaces by blunt dissection.

Jarvis, Myers, and Platt wrote:

"The blunt dissection of the rectum from its loose sacral attachments is not considered complete until the sacral promontory is felt beneath the dissecting finger. We have preferred a hockey stick incision with its vertical arm on the side of greatest involvement. Since Colcock has reported osteomyelitis and pain on pressure as late complications from resection of the coccyx, we have avoided it except in 1 patient whose distal sacral segment and coccyx were fractured by the passage of the missile. After division of the fascia propria and blunt dissection of the rectum away from its areolar attachments to sacrum, soft rubber drains

are passed up to or above the level of the perforation

Bradford Battle and Pasachoff had 28 cases of wounds of the extraperitoneal portion of the rectum, with 1 death. They said

In extraperitoneal rectal wounds adequate drainage is most important and this may necessitate removal of the coccyx. Drainage through the gluteal muscles should be avoided where possible. In all rectal wounds, whether intraperitoneal or extraperitoneal a proximal colostomy should be performed to prevent further soiling and to allow for healing of the injured part.

Laufman in 35 consecutive cases of battle injuries to the extraperitoneal part of the rectum had 3 deaths, only 1 of which was due to the rectal wound. Except for the injuries of one patient first seen 6 days after wounding and in excellent condition these wounds were treated by colostomy complete débridement of the tract and adequate incision of the rectal portion of the endopelvic fascia (fascia propria) with suture of the rectal wall when the defect was large. Coccygectomy was reserved for the most part, for those patients who had a damaged coccyx.

We had 17 patients with extraperitoneal wounds of the rectum one of them died. The condition of the patient we lost was so poor that all we could do was to perform proximal colostomy and establish some degree of drainage from the rectal wound to the outside. We were unable to do any débridement of multiple fractures the patient later died of gas gangrene in these wounds.

We treated our patients by proximal colostomy and wide drainage of the rectal wound and the retrorectal tissue spaces never omitting either step. If adequate exposure or drainage was interfered with by the coccyx we performed coccygectomy. In some cases the wound in the rectum was sutured in others, it was left open.

The site of colostomy should be in the left inguinal region and the sigmoid colon should be utilized. If there is severe damage of the rectum and if the sigmoid colon might be needed later on for repair or reconstruction of the rectum the transverse colon should be utilized for colostomy. The same is true if there is much swelling of the mesosigmoid from gas or hemorrhage which might threaten obstruction or impairment of the blood supply. If the colon has been exteriorized proximal to the rectum for a more proximal wound in the colon this one colostomy is sufficient so long as the fecal stream is diverted from the rectum. Hurt declared

Communication with surgeons in Base Hospitals has revealed that loop colostomy for rectal

injuries has failed in many instances, to completely divert the fecal current. Consequently patients with rectal injuries have arrived with fecally contaminated buttock wounds, and the rectum filled with feces.

The loop probably should be completely divided for rectal wounds of severity when complete diversion of the fecal current from the rectal wound is particularly wanted. The complete division defunctions the distal segment better than does the partially divided loop.

Coccygectomy is certainly not necessary in all cases. We and many others have drained extraperitoneal wounds successfully without it. The indications for its use in the early treatment of rectal wounds are not clear to us as yet. We did not have the opportunity of following our patients long enough to determine whether or not complications arose by our not using it. We did coccygectomy in 5 of our 17 cases of extraperitoneal rectal wounds. Coccygectomy was employed when ever exposure was interfered with by the coccyx in the establishment of drainage or when the coccyx was injured. Our drainage probably was in adequate in one case in which we received a report that coccygectomy had been performed at a hospital in the rear. From those who carried out definitive treatment probably will come the answer as to when coccygectomy is necessary. There is little written about it. Hurt wrote Colcock has reported that osteomyelitis of the sacrum has been a frequent complication of coccygectomy in those with rectal wounds. Croce and associates, who carried out definitive treatment think coccygectomy should be used in all wounds of the extraperitoneal portion of the rectum. Roettig, Glasser and Barney rendered definitive treatment to 9 patients with rectal wounds produced by missiles perforating the sacrum, or sacrum and coccyx. Osteomyelitis developed in most of these patients, and was a problem. Excision of the coccyx by Roettig and associates was an important step in the surgical treatment of these patients in order to obtain exposure of the rectum. These cases of Roettig and associates bring up the question of closure of the rectal perforation.

All writers agree that intraperitoneal rectal wounds should be closed in all cases, when this is possible. However concerning the closure of extraperitoneal wounds, there is still disagreement. In regard to extraperitoneal wounds, Jarvis and associates wrote. No attempt has been made to suture lacerations of the rectum since early experience demonstrated that these suture lines do not hold. In fact additional rectal wall may be sacrificed by its inclusion in the suture. Adequate

drainage of the pararectal fascial spaces is secured, following which the rectal wall heals itself." Morgan said. A wound of the extraperitoneal portion of the rectum should not be sutured. He gave no reasons for this idea. The other men reporting large series from World War II either have employed suture or have not mentioned it. We sutured the extraperitoneal rectal wounds in many cases, but do not know the fate of our sutured wounds.

Two important facts stand out. First, many wounds in the extraperitoneal portion of the rectum do not heal spontaneously even after the performance of proximal colostomy and institution of retrorectal drainage. Chronic fistulas develop. Croce and associates said. Such fistulae, once well established, rarely heal spontaneously and require excision or at least closure on the internal orifice in the bowel wall. In the majority of the 9 cases of transsacral perforation of the rectum reported by Roetting and his associates the wounds did not heal spontaneously. In some of these, infection of the bone prevented healing. Also, there was a marked tendency for the rectal mucosa to evert and proliferate in front of the sacrum and along the sinus tract.

Second, in some cases, the suture lines do hold in extraperitoneal wounds of the rectum, without the formation of a fistula. Croce and his associates cited such cases, and believed that all extraperitoneal wounds should be sutured primarily. It seems most reasonable, therefore, to suture these wounds in the rectum at the first operation to prevent the formation of fistulas which might delay the healing of wounds, increase morbidity and necessitate extra operations.

Complications of wounds of the rectum. The chief complications of wounds of the rectum are peritonitis and retrorectal infection, as already considered herein. Fistulas between rectum and skin or rectum and bladder are rather common. Osteomyelitis of the sacrum, coccyx, and other fractured pelvic bones occurs. Hemorrhage can be severe. Usually it is associated with those patients who have not been properly treated and have severe infection. Although injury to the bladder is not a complication, but an accompanying injury it is one which if overlooked can be most serious. This possibility always should be kept in mind because it is well known that it is often missed. It was the only known injury to an important viscus which we overlooked at laparotomy in our series of large intestinal wounds, and it resulted in a fatality. It is possible for a damaged although not perforated bladder to break down later. If a damaged bladder ruptures into the

peritoneal cavity the prognosis is grave. If it ruptures into the rectum, a rectovesical fistula is established. This latter condition responds well to suprapubic cystostomy combined with the usual treatment of the rectal wound.

CASES IN THE PRESENT SERIES CONSIDERED ACCORDING TO ANATOMIC REGION OF INJURY TO THE LARGE BOWEL

The exact site at which the large bowel is injured plays such an important part in the type of operation to be employed and in the results to be expected that the cases have been arranged in groups according to the anatomic sequence of the lesions. The entire series constitutes a total of 70 cases, in which there were 19 deaths. Two of the deaths are classed as nonoperative since the patients never recovered from shock sufficiently to make it possible for them to undergo a surgical procedure. The 17 postoperative deaths produced a postoperative mortality rate of 25 per cent. In Table XV is shown our over-all mortality rate (27.1 per cent) associated with injuries of the large intestine, both intraperitoneal and extraperitoneal.

Injuries of the cecum. Three patients had injuries to the cecum alone; none died. One patient had injuries to the cecum and small intestine which were not fatal. There were 3 other cases, not included in this group in which there was injury to the cecum, which was distinctly secondary to the major injury of another part of the colon. These 3 cases are included in the cases, respectively of injury to the ascending, descending, and sigmoid colon.

Two (Cases 2 and 4) of the 4 cases included in this section involved simple contusion without perforation, for which nothing was done. It has been our experience that severe contusions of the colon caused by high velocity missiles are potentially dangerous, and that ischemia and, later perforation may result. The consequence of such an event might be peritonitis or retroperitoneal cellulitis and the formation of abscess. Accordingly contusions of the bowel are included in these figures because in other cases expectant treatment was instituted. The inability to predict what will happen to a contused portion of large bowel and the dangers of subsequent ulceration make it safer to exteriorize the involved portion of the cecum. This was true particularly in Case 2.

In the other 2 cases (1 and 3) the cecum was frankly perforated and the holes were closed. One patient was treated by exteriorization, and the exteriorized portion opened spontaneously on the second postoperative day to form a cecal stoma. In the other case the cecum was not exteriorized,

although exteriorization would have been safer. The surgeon chose to exclude the two extraperitoneal holes from the general peritoneal cavity after he had closed the openings, and he drained the retroperitoneal space through a separate stab wound. The patient was observed for 17 days before evacuation and neither infection nor fecal fistula developed.

The size and the location of the cecum which lies more or less protected by the concavity of the ilium probably account for the low incidence of cecal injuries. They also explain why 50 per cent of injuries to the cecum were associated with compound fractures of the ilium. All of the 4 patients did well which might have been expected for in none was there extensive spilling of the fecal contents or spreading peritonitis. The lack of any uniformity in treatment plus the absence of complications, should not imply that the cecum can be treated with impunity for we cannot draw sound conclusions from observations based on a group this small.

It is our feeling that the best plan of treatment involves two features. The first is exteriorization of the damaged portion and the second is drainage of its retroperitoneal bed if that area is injured. It is perfectly safe and desirable to suture the holes before exteriorization and to leave them unopened in the hope that cecostomy can be avoided. The cecum is brought out through a McBurney incision of generous size and the wall of the cecum is tacked to the peritoneum at a safe distance proximal to the sutured holes. When possible no sutures should be used so as to minimize leakage from the sutured cecum into the peritoneal cavity. Iodoform gauze or vaseline packing is then placed so as to encircle the base of the protruding cecum, and this helps to seal off the peritoneal cavity and to keep the wound open.

Tube cecostomy has been employed with success in some of these wounds of the cecum. Hurt treated 3 patients who had single perforations in the right part of the colon or in the cecum by making a stab incision in the abdominal wall. He then inserted a tube into the colon wound and brought the tube with a 2 cm rim of adjacent colon wall out through the stab wound. This prevents any subsequent leakage into the peritoneal cavity. He proposed to close the colonic fistula at a secondary operation without entering the peritoneal cavity.

Jarvis and his associates wrote that they treated small perforations, particularly of the cecum and ascending part of the colon by suturing the colonic wall about a 1 inch (2.5 cm) rubber tube and securing it to the deep fascia by interrupted

TABLE XV—MORTALITY RATE, ACCORDING TO SITE OF INJURY IN 70 CASES OF WOUNDS OF LARGE INTESTINE PRESENT SERIES

Site	Cases	Deaths	
		Number	Per cent
Colon	43	14	31.
Extraperitoneal rectum	17	1	5.9
Intraperitoneal rectum	6	4	66.7
Rectum (site undetermined)			
Totals	70	9	12.8

*Two of the 10 deaths are nonoperative, as explained in the text of this paper.

sutures. When through-and-through wounds were present—that is a perforating wound of the anterior wall and the posterior wall of the cecum—they have sutured the posterior wound and converted the anterior wound into a cecal stoma by this tube method. They removed the cecostomy tube about 6 days postoperatively and drainage ceased a few days later. They used this tube technique successfully.

Injuries of the ascending colon (Table XVI) One other case (Case 43) is not included in this group because the injury to the ascending colon was distinctly secondary to the major injury in the sigmoid colon. This one case, therefore, is included in the cases of injury to the sigmoid flexure.

Wounds of the right portion of the colon present more problems than do wounds of any other section of the colon. This is because the ileum is the segment proximal to the right side of the colon. To deviate the fecal stream from the right side of the colon the ileum must be utilized which, of course, is not true when it is desired to divert the fecal stream elsewhere in the colon. To divert the fecal stream ileostomy or ileocolostomy is necessary.

Ileostomy has many objectionable features. After it has been performed there can be severe loss of fluid and nutrition. Ileal feces are most irritating to wounds and also to the normal skin. There is increased danger of breakdown of the wounds and dehiscence. Although we know of cases in which ileostomy was successfully employed in wounds of the right side of the colon we think ileostomy should not be used if it can be avoided.

Ileocolostomy however is a valuable procedure. When ileocolostomy has been performed loss of fluid and nutrition does not take place, there is no spillage of irritating contents on the abdominal wall and the formidable nursing problem disappears. An ileocolic anastomosis heals

TABLE XVI.—INJURIES TO THE TRANSVERSE COLON STRUCTURES INVOLVED IN 5 CASES
PRESENT SERIES

Structure involved	Cases	Deaths
Transverse colon alone		
Transverse colon and jejunum		
Transverse colon, jejunum, and liver

much better than does a colon-to-colon anastomosis. The indications for ileocolostomy will be discussed later.

Cecostomy is the most common method used to divert the fecal stream away from wounds of the ascending portion of the colon. When a cecal stoma is used thus as a proximal vent, it should be large if much diversion of the fecal stream is desired. If complete diversion of the fecal stream is desired, cecostomy will be inadequate.

Because there is this difficulty of diversion of the fecal current in wounds of the right portion of the colon, there is a greater tendency toward more radical treatment and resection of such wounds. We feel, as we have already made clear herein, that resection should be avoided whenever possible. This decision was based in part on the 4 instances in which primary resection was performed in our group of 8 cases of wounds of the ascending colon. Primary resection is too shocking in an operation in most cases of abdominal wounds. We think the simpler procedures are better if they suffice to handle the situation.

The procedure chosen often depends on the condition of the patient. It must not be forgotten that a patient who has been or is in shock after wounding is a poorer risk than one who has not been in shock. In abdominal wounds, the mortality rate varies directly with the degree of shock present. When the patient's general condition has been good before operation, and it appears he can tolerate the surgical treatment needed for all his wounds, then exteriorization in most cases is the method of choice. It should be done in almost all cases of large, severe wounds. In these large wounds, we think that the danger of the wound breaking down is too great to justify suture.

When the patient's general condition is poor, exteriorization with the extensive mobilization so often necessary to accomplish this, should not be done if a less shocking procedure can be safely sub-

stituted. Small and medium-sized wounds can be sutured. The suture should be accompanied by the added safety of cecostomy. The larger the wound sutured, the more generous the cecostomy should be. In a small wound, if suture alone is the procedure chosen, a drain should be used when cecostomy is omitted. A suture line is made safer by suture of the omentum or an epiploic appendix over the suture line.

Retropertitoneal wounds of patients who constitute a good risk probably should be exteriorized by mobilization of the colon, and then by bringing the wounded loop of bowel out onto the anterior abdominal wall. When such a procedure is used, the retropertitoneal spaces should be drained through a stab wound in the back to prevent the formation of a retrocolic abscess which often forms after such exteriorizations. When patients who are poor risks have retropertitoneal wounds, a generous tract should be established from the flank or back down to the wound in the colon. Dependent drainage should be instituted. The wound in the colon should be sutured, if possible. Then the patient should be turned, the peritoneal cavity should be explored through an abdominal incision, and cecostomy should be performed. A mushroom catheter has been sutured into the wounded part of the colon and brought out through a stab wound posteriorly with success in some retropertitoneal wounds.

In most cases, resection should be considered only as a last resort. In the presence of very severe damage to a large segment of the ascending colon, resection of the damaged segment, with exteriorization of the open ends of the colon, is a wise procedure. Right colectomy might be necessary in a very extensive wound of the right part of the colon but should be avoided if possible. The procedure is too shocking in most cases. If the general condition of the patient is good and the surgeon is experienced, this operation might be the best way out of a bad situation. If right colectomy is performed, ileotransversostomy should be performed at the same time, and the proximal open end of the transverse or ascending colon should be brought out through a stab wound to act as a safety valve for the anastomosis. We think that the ends of the ileum and colon should not be brought out as in spur ileocolostomy. This procedure has the bad features of an ileac stoma. A more detailed account of our own and others' experience with resection has been presented herein in the section on operative treatment of wounds of the rectum.

Injuries of the hepatic flexure. We had 3 patients with injuries of the hepatic flexure, and it is

interesting that in all 3 cases the kidney and liver were wounded in addition to the hepatic flexure. One of the 3 patients died. Wounds of the hepatic flexure should be exteriorized if the patient's condition permits it. This must be done when severe wounds are present, even if the patient's condition is poor. Mobilization is relatively simple in this part of the colon. If the wound in the colon is not severe and the patient's condition is poor then suture of the wound with performance of cecostomy is adequate. In case 13, the perforation in the exteriorized loop of bowel was sutured at the primary operation and remained closed.

Drainage of the subhepatic area should be done in these cases to prevent the development of subdiaphragmatic abscess. We did not institute such drainage in case 13 at the primary operation and a subdiaphragmatic accumulation of bile developed. This necessitated drainage through an Ochsner incision.

Injuries of the transverse colon. The 5 cases in this group are shown in Table XVI. Other cases in which there was injury to the transverse colon which was distinctly secondary to the major injury of another part of the colon are 5, 11, 35, 39 and 66. They do not comprise the 5 cases in this section.

Wounds of the transverse colon are easily handled for exteriorization without mobilization often is possible. Exteriorization is the method of choice. In case 18 successful closure of a wound in an exteriorized loop of bowel was done at the first operation. The patient was out of the hospital and well only 3 weeks after his injury. The patient in case 19 was treated by suture alone without complications. We believe it would have been wiser to exteriorize the sutured loop of bowel. The one patient who died (case 20) was properly treated but died despite treatment.

Injuries of the splenic flexure. These injuries, comprising 9 cases, are listed in Table XVII. The splenic flexure is the most difficult part of the colon to inspect, mobilize and exteriorize because of its inaccessibility. The spleen often is injured in addition to the flexure and splenectomy sometimes is necessary. Thus considerable surgical treatment often is indicated. We employed exteriorization in some cases and suture of the wound combined with transverse colostomy in others. We think the simpler procedure is better if the patient is not in good general condition. When severe wounds are present exteriorization is compulsory.

A Mikulicz type of colostomy was used in one case in which the flexure was completely divided by the missile.

We think drainage of the left upper abdominal quadrant is desirable and that it should be dependent through a stab wound in the flank. In case 29 such drainage was not established and an abscess developed in the left upper abdominal quadrant and the patient died as a result. The death in case 28 probably was unavoidable. However, this patient might have been saved if he had been operated on and if an active bleeding point had been found and the bleeding controlled. This type of desperate case in which the patient does not respond well to shock therapy has been discussed herein in the section on the management of patients in desperate condition.

Among the structures injured in addition to the splenic portion of the colon is the diaphragm. It is most important to close any opening into the pleural cavity to prevent empyema. We had one patient in Italy in whom such a small diaphragmatic perforation was not closed, and empyema developed.

Injuries of the descending colon. The 8 cases in this group are listed in Table XVIII. Case 28 in which there was a wound of the splenic flexure is included in the section on injuries to that part of the colon and not in the present section although in this case the descending colon was damaged severely in the proximal part. The descending colon like the splenic flexure is inaccessible. In the mobilization of it and exteriorization of a damaged portion of it additional serious damage can be done to an already ill patient. However, some wounds must be exteriorized and in almost all our cases this treatment was used. In 2 cases, we think less surgical treatment might have given the patient a better chance of survival. The patient in case 37 had a retroperitoneal wound in both the right and left parts of the colon. Both

wounds were exteriorized only after long and extensive mobilization, which was enough to send the patient in shock, from which he never recovered, in spite of the repeated transfusion of blood. He could have been treated faster and less traumatically by the establishment of drainage down to the wounds in the colon, retroperitoneally through the flanks. He could then have undergone exploratory celiotomy with the establishment of an ileosigmoid anastomosis to deviate the fecal stream from the wounds in both the right and left portions of the colon. The condition of the patient in case 35 was desperate: there was a large intraperitoneal wound in the descending colon and a small wound in the transverse colon. We exteriorized the wounded part of the descending colon, the patient went back into profound shock and died. Our only alternative in such an instance would be to suture the large tear in the descending colon and exteriorize the wounded segment of transverse colon to deviate the fecal stream from the wounded part of the descending colon. In the suturing of such a large wound as this, we believe there is considerable danger of breakdown, although Gordon-Taylor reported that a wound 6 cm. long in the descending colon was sutured without complications.

Case 33 perhaps needs an explanation. The patient had sustained incomplete transection of the descending colon at its juncture with the splenic flexure. While the colon was being mobilized for a colostomy the patient went into shock. To cut the procedure short, the colon was divided completely and the end of the proximal segment was brought out through a subcostal stab wound. The open end of the distal segment was brought out through the wound in the back caused by the missile. This probably made the problem of re-establishment of the continuity of the colon more difficult for the surgeons at the base hospital. However to have continued mobilization of the splenic flexure and descending colon until

we could exteriorize both ends through a single wound would have been too shocking. Even after the shortened procedure, this man was very sick for a few days. On the basis of the reports already considered in this article, it would seem that reconstruction work on wounds of the colon can be accomplished with almost no mortality. Thus, the primary operation has as its prime purpose the saving of the life of the patient.

Injuries of the sigmoid colon. The 8 cases of wounds in this anatomic region are listed in Table XIX. We think externalization is most satisfactory as a rule in the treatment of wounds of the sigmoid flexure. All of our patients except 2 were treated by this method. The patient in case 39 had wounds of the transverse colon; hence, he was treated by suture of the wound in the sigmoid and performance of transverse colostomy. We think it is sound surgery to employ suture with proximal colostomy in such a case. The sutured wound was of moderate size. Although from the record we cannot determine whether the loop of transverse colon was opened, we feel certain it was, because our policy was to defunctionalize a distal wounded segment of bowel in such a case.

The 3 deaths in this group require no comment, with the possible exception of the death in case 45. The patient was not operated on because of severe shock. We have considered problems such as this in the section on the management of patients whose condition is desperate.

Injuries of the rectum. The 6 cases of wounds of the intraperitoneal part of the rectum and the 17 cases of wounds of the extraperitoneal part of the rectum are listed in Table XX. In cases 64 and 65 it was not possible to determine the exact site of injury in the rectum.

Wounds of the intraperitoneal part of the rectum were treated by proximal colostomy and suture of the wound in the rectum. We had 6 cases of perforating wounds, and in 4 of these cases the wounds were complicated by injuries to multiple organs. All of the 4 patients died. The patient in case 66 had severe multiple abdominal injuries and a severe penetrating wound in the head. It was thought at autopsy that the chief cause of death was the wound in the head. The condition of the patient in case 67 was desperate: the patient did not respond to shock therapy and died during induction of anesthesia. His only chance was in operation. The patient in case 68 likewise was in desperate condition: he had been admitted in a state of severe shock, and responded poorly to shock therapy. He had massive fecal contamination of the peritoneal cavity. Death ensued shortly after operation: it was caused by the

severe shock in association with peritonitis. We believe that these 3 patients were properly handled and that death was inevitable.

In case 70 death resulted from the fact that a wound in the bladder had not been recognized at operation. This man withstood the operation fairly well. The rectal perforations were sutured. A urinary fistula developed postoperatively. We believe that the drainage of urine over the rectal sutures caused the wounds to break open and fecal fistulas to develop. Sepsis and hemorrhage occurred and death resulted.

Injury to the bladder commonly is associated with wounds of the rectum. Such injury was an associated lesion in 20 per cent of our 25 cases of wounds of the rectum, and was disastrous in the case in which we failed to detect it. Thus, it should be looked for carefully in rectal injuries. Cystoscopy carried out postoperatively allowed us to detect a suspected perforation of minute size in one case. Suprapubic cystostomy is indicated when a perforation of the bladder exists.

The small bowel also was injured in 4 of our 6 cases of injury to the intraperitoneal part of the rectum which made the condition more serious.

In our 17 cases of injuries to the extraperitoneal portion of the rectum there was but one death. These excellent results are due to our insistence on performance of proximal colostomy in every case combined with the institution of generous drainage of the spaces about the rectum. Furthermore, these wounds were not associated with injuries to multiple organs to the same extent as was true in the cases of injuries to the intraperitoneal part of the rectum. The small bowel was involved only once, and the bladder 3 times. The rectum was the only abdominal organ injured in 11 cases of injuries to the extraperitoneal part of the rectum.

Our one death in this group of wounds of the extraperitoneal part of the rectum occurred in Case

69. The patient had sustained severe fractures, and débridement and rectal drainage had not been done thoroughly because the surgeon considered the patient's general condition to be too poor. Gas gangrene developed and the patient died. At autopsy severe pulmonary fat embolism was found. This, combined with traumatic shock and gas gangrene, accounted for the death.

In the case just described we used transverse colostomy because the mesentery was filled and distended with gas in the pelvis and along the sigmoid flexure. In case 66 transverse colostomy also was used because the patient had a wound of the transverse colon which we exteriorized. Usually sigmoidostomy is best in wounds of the rectum.

Coccygectomy was used in 6 cases in which the coccyx interfered with exposure, or drainage was thought to be inadequate with the coccyx left in place.

Suture of the wound in the rectum was a matter left to the discretion of the individual surgeon. We think that suture should be attempted at the first operation. As we have already shown some of these wounds heal after suture. If the wound stays closed, the main source of contamination—the lumen of the rectum—is shut off from the tissues about the rectum. This is an important step in the right direction.

RÉSUMÉ 70 CASES OF INJURY TO THE LARGE INTESTINE AUTHORS' SERIES

Case	Part Injured	Clinical History	Position between Injury and Operation	Pathologic Findings	Operative procedure	Comment
Cecum	Injured	12-1944 Penetrating wound, abdomen (shell fragment).	6	Two small retroperitoneal lacerations in cecum, spillage in peritoneal cavity.	Cecum mobilized, lacerations closed R (trocar) and drainage; rubber tube and cigarette drain through anterior stab wound.	Evacuated: 2-8-1944.
Cecum	Injured	4-2-1945 Auto accident, thrown against wheel.	44	Severe tear and slight constriction in cecum. Rest of the colon had small punctate hemorrhages. Cecum had two gangrenous areas, differential places, each about 6 in. long, stomach had punctate hemorrhages, type C, bloody fluid in peritoneal cavity and peritonitis with pressure areas of gut adherent to adjacent structures.	Double section of cecum with two end-to-end anastomoses.	Mild bilateral, acute bronchopneumonia. Evacuated: 2-4-45.
Cecum	Injured	4-3-1945 Gun shot wound, perforating right flank, compound comminuted fracture of scapula.	12	Small tear in peritoneum of right lower quadrant, two small wounds perforating cecum. Right wound perforated.	Enlargement, exploration of cecum, lacerations closed, clearly loop of cecum retracted.	Cecum wounds opened spontaneously on and posterior day. Evacuated: 2-2-45 good condition.
Cecum	Injured	11-19-34 Compound comminuted fracture of right ilium.	247	Perforating gunshot wound, wound of entrance in lateral part of left lower quadrant, wound of exit in right buttock. Continuum of diameter on retroperitoneal part of cecum without perforation.	Tract explored, wounds debrided. Cecum left in place, wounded area not treated.	Evacuated: 2-20-1945.
Ileum	Injured	2-8-1945 Multiple wounds, left forearm, left buttock (shell fragment).	12	Compound comminuted fracture right ilium, with perforation of cecum, transverse colon, liver. Cecum was ruptured, long tract extended from cecum into ascending colon.	Right colectomy, ileostomy. Free ends of ileum and colon brought out through abdominal stab wound in right upper quadrant.	Evacuated: 2-20-1945. Follow-up note: bowel well closed off, patient doing well.
Ascending colon	Injured	2-8-1945 Penetrating gunshot wound, abdomen. Paralysis, both lower limbs. Compound comminuted fracture of scapula (fourth lumbar vertebra).	47-48	Cecum perforated, body of fourth lumbar vertebra perforated. Large lacerations through all of ascending colon at ascending border.	Side-to-side ileostomy. Cecum, stump of ileum, ascending colon up to perforation exteriorized. Seven days later resection of redundant cecum and lower ascending colon, without anastomosis.	Evacuated: 2-23-1945.
Ascending colon	Injured	2-10-1945 Gun shot wound, abdomen.	21	Ascending colon perforated just below hepatic flexure, lacerations of liver compound comminuted fracture of right ilium.	Cecum, ascending colon, hepatic flexure mobilized, brought out as loop through right abdominal incision. Two holes in colon sutured, loop left suspended.	Seventh, postoperative day patient doing well, colon loop still suspended. Evacuated: 2-12-1945.
Ascending colon	Injured	2-8-1945 Gun shot perforating, two perforating, one penetrating wounds, lower half of back.		Small perforation, pieces of right chest over each rib, two lacerations of kidney, several tears in ascending colon, compound comminuted fracture of sac, and 3rd lumbar vertebra and of left and right ribs. Damage to spinal cord.	Excision of right rib, closure of pleura. Mobilization of ascending colon for inspection. Suture of lacerations of kidney and ascending colon.	Evacuated: 2-27-1945.
Ascending colon	Injured	2-3-1945 Severe wound right lateral lumbar region of back (shell fragments).	21	Retroperitoneal wound, ascending colon draining in flank. Wounds, right arm, thigh.	Ascending colon, cecum resected. Ileum sutured to transverse colon; end of transverse colon brought out through right abdominal stab wound.	Jaundice, subacute cholecystitis of main abdominal wound. Evacuated: 2-2-1945.
Ascending colon	Injured	2-12-1945 Wounds, right eye, right arm, right thigh, both legs (shell fragments).	20	Retroperitoneal hemorrhage lateral to ascending colon. Small perforations, middle part of retroperitoneal sac, ascending colon. Right iliac crest fractured.	Ascending colon sutured. Hole in colon sutured, loop colectomy.	Evacuated: 2-3-1945 bowel suture has still intact.

RÉSUMÉ 70 CASES OF INJURY TO THE LARGE INTESTINE AUTHORS' SERIES—Continued

Case	Part Injured	Clinical history	Hours between injury and operation	Pathologic findings	Operative procedure	Comment
	Ascending colon	Injured 1 9-044. Rigid, tender abdomen, complete paralysis right lower extremity, partial paralysis of left.	14	Perforating wound abdomen (shell fragment). Peritoneal cavity filled with much dark, fecal-smelling bloody fluid; generalized peritonitis present. Ascending colon perforated twice, was dark, discolored, moderately infiltrated with fecal drainage. One small perforation in transverse colon. Compound fracture, humerus vertebra.	Resection of terminal ileum, cecum, ascending colon and proximal transverse colon. Open ends of transverse colon and ileum sutured in approximation, brought out together as spur through stab wound in right upper quadrant.	Patient died in shock 48 hours after operation. Was in severe shock at end of operation. Necropsy not performed. It is thought to be due to peritonitis and shock.
	Ascending colon	Injured about 17 044. At autopsy, blood pressure not obtainable.	At least 9	Bullet traversed 5th lumbar vertebra, fractured right iliac crest. Large perforation in posterior aspect of cecum, also perforation in sigmoid process in cecum, ascending colon.	Right colectomy. Neotransverse colectomy; proximal end of colon brought out through stab wound. At end of operation, patient's condition very poor.	Patient died 14 hours after operation. Shock, sepsis thought the causes of death.
13	Hepatic flexure	Injured 3-16-045. Wound of back (shell fragments).	13	Fracture 4th lumbar vertebra, contusion right kidney perforation hepatic flexure of colon, perforation right lobe of liver.	Ascending colon and hepatic flexure mobilized, holes in hepatic flexure closed. Transverse flexure exteriorized as loop colectomy. Subphrenic space not drained.	Subdiaphragmatic accumulation of bile developed, was drained. Evacuated; 3-20-045.
14	Hepatic flexure	Injured 6-30-045. Penetrating gunshot wound, right chest.	3	Bullet entered hepatic flexure of colon in intraperitoneal part; came out in extraperitoneal part, entered right kidney in upper pole, nicked liver.	Doorslager was mobilized, no wound closed. Hepatic flexure including wounded segment, anteriorized.	Evacuated, 7-0-1945. Report on 8-3-045 Patient doing well. Colectomy at this time about to be closed.
15	Hepatic flexure	Injured 3-12-1945. Small right hemothorax; this was aspirated. Scurry paralysis below level of 5th thoracic vertebra.	At least 24	Bone fragments driven into cauda equina. Right diaphragm, liver retroperitoneal part of hepatic flexure perforated; right kidney severely contused.	Hepatic flexure mobilized, perforations sutured, damaged segment anteriorized as loop colectomy. While bladder was being distracted for suprapubic cystostomy patient suddenly died.	Necropsy: bloody secretions partially obstructing bronchi, atelectasis, edema of right, left lower lobes; also contusion of right lower lobe.
16	Transverse colon	Injured 30-045. Penetrating gunshot wound.	13	Two perforating wounds in jejunum; two in transverse colon.	All four perforations in bowel closed. Perforated area of transverse colon exteriorized.	Evacuated 4 7 1945; in good condition.
17	Transverse colon	Injured 9-045. Perforating gunshot wound, abdomen.	3	Perforation, left part of transverse colon, sceral tear in jejunum. Right lobe of liver perforated.	Transverse colon exteriorized. 1 jejunum and liver were drained through right flank wound.	Evacuated; 9 10 45; in good condition.
18	Transverse colon	Injured 3 17-045. Gunshot fragments. Penetrating wound, abdomen; small piece of intestine herniated through abdominal wound.	4	Perforation; transverse colon, cna. diameter. Perforation, cna. diameter. Posterior surface stomach, cna. diameter. Laceration cna. tail of pancreas. Splenic vein lacerated; prolate hemorrhage encountered. Retroperitoneal hemorrhage in left kidney region.	Perforations in stomach, colon sutured. Splenectomy. Suture of peritoneum over pancreas. Injured loop of transverse colon exteriorized.	Suture line in colon never broke down. 7 days post-operatively enteropneumothorax of colon was freed from abdominal wall, replaced in peritoneal cavity. On 7-045 patient discharged in excellent condition. All wounds completely healed.
19	Transverse colon	Injured 10-7-045. Multiple penetrating small wounds (shell fragments).	13	Two gunshot perforations, 1 anastomosis col. Compound comminuted severe fracture, left humerus, accompanied by left radial nerve injury.	Wounds in transverse colon sutured; colectomy not performed.	Evacuated, 10-30-045.
20	Transverse colon	Injured; 4 045. In severe shock 3 arterial lacer.	3	Gunshot wound, perforating right chest wall through peritoneal cavity into left retroperitoneal space in left lower quadrant. Diaphragm lacerated, but pleural cavity not penetrated. Transverse colon perforated twice, jejunum four times; stomach twice. Laceration of small bladder; small laceration of liver. Generalized peritonitis. Compound fracture, left femur.	Holes in large bowel, stomach, small bowel sutured. Cholecystectomy. Transverse colon exteriorized. Patient never recovered from shock; died 30 hours after operation.	Necropsy: moderate atelectasis of lower lobes of both lungs.

RÉSUMÉ: 70 CASES OF INJURY TO THE LARGE INTESTINE. AUTHORS' SERIES

Case	Part Injured	Clinical history	Hours between injury and operation	Pathologic findings	Operative procedure	Comment
	Cecum	Injured: 11-3-1944. Penetrating wound, abdomen (shell fragments).	6	Two small retroperitoneal holes in cecum, spillage in peritoneal cavity.	Cecum mobilized; holes sutured. H (reperitoneal) drainage rubber tube and cigarette drain through anterior side wound.	Evacuated: 12-4-1944.
	Cecum	Injured: 4-27-1943. Auto accident; three gunshot wounds.	64	Several tear and sharp contusions on cecum. First of the cecum had small punctate hemorrhages. Drains led two gangrenous areas of different places, each about 8 in. long. Mesosigmoid had punctate hemorrhages, 2,000 bloody fluid in peritoneal cavity; mild peritonitis with gangrenous areas of fat adherent to adjacent structures.	Double resection of cecum with two end-to-end anastomoses.	Mild bilateral, acute bronchopneumonia. Evacuated: 5-45.
1	Cecum	Injured: 4-27-1943. Gun shot wound, perforating right flank. Compound comminuted fracture of iliac crest.	12	Small tear in peritoneum of right lower quadrant. Two small ovoid perforating cecum. East wound parasternal.	Exploration, exploration of w. d. at dry cecum w. d. connected and closed, loop of cecum exteriorized.	Cecum wounds opened spontaneously on end postoperative day. Evacuated: 3-45; good condition.
	Cecum	Injured: 8-1-44. Compound comminuted fracture of right ilium.	22	Perforating gunshot wound, wound of entrance in lig and part of left leg exposed, wound of exit in right buttock. Contusion on distal end of retroperitoneal part of cecum without perforation.	Tract explored, wounds debrided. Cecum left in place; contused area not treated.	Evacuated: 4-20-1945.
2	Ileum	Injured: 4-7-44. Multiple wounds, left forearm, left buttock (shell fragments).		Compound comminuted fracture right ilium, with perforation of cecum, transverse colon, liver. Cecum was everted; loop was extended from cecum into ascending colon.	Right colostomy, debridement. Free ends of ileum and colon brought out thru gl. buccal tab wound in right upper quadrant.	Evacuated: 4-20-1944. Follow-up notes, bowel ends closed off, patient doing well.
3	Ascending colon	Injured: 3-6-1944. Penetrating gunshot wound, abdomen. Parasternal, both lower limbs. Compound comminuted fracture of ilium and tibia (bullet in vertebral).	2-26	Cecum perforated body of fourth lumbar vertebra perforated. Large incision through wall of ascending colon at mesenteric border.	Side-to-side ileotransverse anastomosis. Cecum, strip of ileum, ascending colon up to perforation exteriorized for 10 days later, excision of redundant cecum and lower ascending colon, without anastomosis.	Evacuated: 3-2-1945.
4	Ascending colon	Injured: 4-2-44. Gun shot wound, abdomen.	31	Ascending colon perforated just below hepatic flexure, perforation of liver. Compound comminuted fracture of right ilium.	Cecum, ascending colon, hepatic flexure mobilized, brought out as loop through right abdominal wound. Two holes in colon sutured; loop left suspended.	Branch, postoperative day; patient doing well, colon loop still suspended. Evacuated: 4-2-1945.
5	Ascending colon	Injured: 4-4-44. Gun perforating, two penetrating, gunshot wounds, lower half of back.		Small perforation, places of right chest area with rib fracture. Location of kidney, second hole in ascending colon, compound comminuted fracture of 1st, 2nd, and 3rd lumbar vertebrae and of left and right ribs. Damage to spinal cord.	Resection of right rib; closure of pleura. Mobilization of ascending colon for anastomosis. Suture of lacerations of kidney and ascending colon.	Evacuated: 20-7-1944.
6	Ascending colon	Injured: 10-3-44. Severe wound right lateral lumbar region of back (shell fragments).		Retroperitoneal wound, ascending colon clamped in back. Wound, right arm, thigh.	Ascending colon, cecum resected. Ileum anastomosed to transverse colon; rest of transverse colon brought out through right abdominal side wound.	Asplenic, unknown cause infection of small abdominal wound. Evacuated: 20-22-1944.
7	Ascending colon	Injured: 21-44. Wound, right eye, right arm, right thigh, both legs (shell fragments).	30	Retroperitoneal hemorrhage lateral to ascending colon small perforation, middle part of retroperitoneal wall in ascending colon. Right iliac crest tract red.	Ascending colon mobilized. Hole in colon sutured; loop colostomy.	Evacuated: 4-3-1945. Lower portion less still intact.

RÉSUMÉ 70 CASES OF INJURY TO THE LARGE INTESTINE AUTHORS SERIES—Continued

Case	Part Injured	Clinical history	Hours between injury and operation	Pathologic findings	Operative procedure	Comment
	Ascending colon	Injured. 9-044. Right, tender abdomen, complete paralysis right lower extremity, partial paralysis of left.	74	Perforating wound abdomen (shell fragment). Peritoneal cavity filled with most dirty fecal-matter bloody fluid, generalized peritonitis present. Ascending colon perforated twice, was dark, discolored, necrotic; infiltrated with fecal drainage. One small perforation in transverse colon. Compound fracture, lumbar vertebra.	Resection of terminal ileum, cecum, ascending colon and distal transverse colon. Open ends of transverse colon and ileum sutured in preperitoneum; brought out together as spu. through stab wound in right upper quadrant.	Patient died in shock 18 hours after operation. Was in severe shock at onset of operation. Necropsy not performed but due to thought to be due to peritonitis and shock.
1	Ascending colon	Injured about 7-044. A (v d) p (a) d shock, blood pressure not obtainable.	At least 9	Bullet traversed 5th lumbar vertebra, fractured right iliac crest. Large perforation in posterior aspect of ascending colon. Piles necrotic process involved cecum, ascending colon.	Right colectomy. Necrotic transverse, proximal end of colon brought out through stab wound. At end of operation patient's condition very poor.	Patient died 4 hours after operation. Shock, sepsis thought the causes of death.
13	Hepatic flexure	Injured 3-16-045. Wound of back (shell fragments).	5	Fracture 4th lumbar vertebra, confusion right kidney perforation hepatic flexure of colon, perforation right lobe of liver.	Ascending colon and hepatic flexure mobilized, holes in hepatic flexure closed. If hepatic flexure exteriorized as loop colectomy. Subphrenic spaces not drained.	Subdiaphragmatic accumulation of bile developed, was drained. Evacuated; 3-26-045.
14	Hepatic flexure	Injured 6-20-045. Penetrating gunshot wound, right chest.	5	Bullet entered hepatic flexure of colon in latraperitoneal part; came out in extraperitoneal part; entered right kidney in upper pole, nicked liver.	Duodenum was mobilized, no omentum found. Hepatic flexure, including omentum, was resected.	Evacuated 7-0-045. Report on 8-5-045 Patient doing well. Colectomy at this time about to be closed.
5	Hepatic flexure	Injured 3-16-045. Small right hemithorax. Ribs were aspirated. Sensory paralysis below level of 5th thoracic vertebra.	At least 12	Bone fragments driven into caecum caecum. Right diaphragm, liver, and posterior part of lower lobe of lung perforated; right kidney severely contused.	Hepatic flexure mobilized, perforations sutured, damaged segment exteriorized as loop colectomy. With bladder was being deferred for suprapubic cystostomy patient suddenly died.	Necropsy: bloody secretions partially obstructing bronchi; atelectasis, edema of right, left lower lobes, also contusion of right lower lobe.
6	Transverse colon	Injured 4-20-045. Penetrating gunshot wound.	1	Two perforating wounds in jejunum; two in transverse colon.	All four perforations in bow were closed. Perforated area of transverse colon exteriorized.	Evacuated 4-7-045 in good condition.
7	Transverse colon	Injured 5-10-045. Perforating gunshot wound, abdomen.	3	Perforation, left part of transverse colon; serosal tear in jejunum. Right lobe of liver perforated.	Transverse colon exteriorized. 1 lue in t d. Liver area drained through right flank wound.	Evacuated 5-4-045 in good condition.
18	Transverse colon	Injured 5-7-045. Gunshot wound, penetrating wound, small piece omentum herniated through abdominal wound.	4	Perforation; transverse colon, caecum diameter. Perforating wound, posterior surface stomach, caecum diameter. Laceration on tail of pancreas. Splenic vein lacerated; profuse hemorrhage encountered. Retroperitoneal hemorrhage in left kidney region.	Perforations in stomach, colon sutured. Splenectomy. Suture of peritoneum over pancreas. Injured loop of transverse colon exteriorized.	Suture line in colon never broke down, 17 days post-operatively exteriorized loop of colon was freed from abdominal wall, replaced in peritoneal cavity. On 7-045 patient discharged in good condition. All wounds completely healed.
9	Transverse colon	Injured 0-17-044. Multiple penetrating small wounds (shell fragments).	12	Two minute perforations, 1 in 2nd area. Compound comminuted severe fracture, left humerus, accompanied by left radial nerve injury.	Wounds in transverse colon sutured; colectomy not performed.	Evacuated 0-20-044.
20	Transverse colon	Injured, 4-045. In shock 4 arrival at local.	5	Gunshot wound, perforating right chest wall through peritoneal cavity into left rectum muscle in left lower quadrant. Diaphragm lacerated, but pleural cavity not penetrated. Transverse colon perforated twice; jejunum four times, stomach twice. Laceration, laceration of gall bladder, small laceration of liver. Generalized peritonitis. Compound fracture, left femur.	Holes in large bowel, stomach, small bowel sutured. Cholecystectomy. Transverse colon exteriorized. Patient never recovered from shock; died 20 hours after operation.	Necropsy: moderate atelectasis of lower lobes of both lungs.

RÉSUMÉ 70 CASES OF INJURY TO THE LARGE INTESTINE. AUTHOR'S SERIES.

Case	Part injured	Clinical history	Hours between injury and operation	Pathologic findings	Operative procedure	Comment
1	Cecum	Injured: 7-12-1944. Feces exiting wound, abdomen (shell fragments).	6	Two small retroperitoneal holes in cecum, spillage in peritoneal cavity.	Cecum mobilized, holes sutured. Retroperitoneal drainage rubber tube and cigarette drain through as lower stich wound.	Evacuated 12-8-44.
2	Cecum	Injured: 4-22-45. Acute ecchymotic thromos against wheel.	6 1/2	Serious tear and slight contusion in cecum. Rest of the colon had small perforations hemorrhages; found two perforations areas at different places, each about 6 in. long; stomach had punctate hemorrhages 2,000. Bloody fluid in peritoneal cavity and pus; locusts with coagulation areas of gut adjacent to adjacent structures.	Deeply resection of ileum with two end-to-end anastomoses.	Mild bilateral acute bronchopneumonitis. Evacuated 7-45.
3	Cecum	Injured: 8-8-45. Occasional wound, perforating right flank, compound comminuted fracture iliac crest.	13	Small tear in peritoneum of right lower quadrant, two small wounds perforated cecum. Exit wound perineal.	Exploration, exploration of area distal to entry site closed; loop of cecum resected.	Cecum wounds opened spontaneously on second postoperative day. Evacuated 8-14-45 good condition.
4	Cecum	Injured: 2-8-1945. Compound comminuted fracture of right thorax.	2 1/2	Perforating gunshot wound, wound of entrance in lateral part of left lumbar quad muscle, wound of exit in right buttock. Contained one fragment in retroperitoneal part of cecum without perforation.	Trajectory explored, wounds debrided. Cecum left in place, contained area not treated.	Evacuated 4-28-45.
5	Cecum	Injured: 2-8-45. Melted in wounds, left (entry) left buttock (shell fragments).	12	Compound comminuted fracture right ilium, with perforation of cecum, transverse colon, liver. Cecum was entered long time extracted from cecum hole as crading colon.	Right colostomy, ileocecal anastomosis. Two ends of ileum and colon brought out through abdominal wall.	Evacuated 2-28-1945. Follow-up notes: bowel and chest ok, patient doing well.
6	Ascending colon	Injured: 2-6-45. Perforating gunshot wound, abdomen. Paralysis both lower limbs. Compound comminuted lrs. are located fourth lumbar vertebrae.	2-26	Cecum perforated, body of fourth lumbar vertebrae perforated. Large laceration through wall of ascending colon at mesenteric border.	Side-to-side ileotransverse-anastomosis. Cecum, transverse colon, ascending colon up to perforation exteriorized. Seven days later excision of redundant cecum and lower ascending colon, without anastomosis.	Evacuated 2-27-45.
7	Ascending colon	Injured: 4-8-45. Gun shot wound, abdomen.	3	Ascending colon perforated just below hepatic flexure, laceration of lower compound comminuted fracture of right ilium.	Cecum, ascending colon, hepatic flexure mobilized, brought out as loop through right iliofemoral incision. Two holes in colon entered, loop left unopened.	Seventh, postoperative day patient doing well, colon loop still unopened. Evacuated 4-12-1945.
8	Ascending colon	Injured: 10-4-1944. One perforating, two penetrating gunshot wounds, lower half of back.		Small perforation, pieces of right chest over sixth rib. Two lacerations of kidney, several tears in ascending colon, compound comminuted fractures of 1st, 2nd, and 3rd lumbar vertebrae and of left and right ribs. Damage to spinal cord.	Resection of right rib, closure of pleura. Mobilization of ascending colon for laparotomy. Resection of lacerations of kidney and ascending colon.	Evacuated 10-7-1944.
9	Ascending colon	Injured: 4-3-45. Severe wound right lateral lower region of back (shell fragments).		Retroperitoneal wound; ascending colon draining in back. Wounds right arm, thigh.	Ascending colon, cecum resected. Ileum entered by transverse colon; end of transverse opened brought out through right iliofemoral stab wound.	Junction, unknown cause, infection of upper abdominal wound. Evacuated 5-22-45.
10	Ascending colon	Injured: 5-12-1945. Wounds right eye, right arm, right thigh, both legs (shell fragments).	30	Retroperitoneal hemorrhage internal to ascending colon. Small perforation, middle part of retroperitoneal surface of ascending colon. Right iliac cord fractured.	Ascending colon mobilized. Hole in colon entered, loop colostomy.	Evacuated 5-17-1945. Bowel nature has still intact.

RÉSUMÉ 70 CASES OF INJURY TO THE LARGE INTESTINE AUTHORS SERIES—Continued

Case	Part Injured	Clinical history	Hours between injury and operation	Pathologic findings	Operative procedure	Comment
	Ascending colon	Injured. 9-144. Right, tender abdomen, complete paralysis right lower extremity partial paralysis left.	14	Perforating wound abdomen (shell fragment). Peritoneal cavity filled with much clotted fecal-staining blood. Fluid, generalized peritonitis present. Ascending colon perforated twice, was dark, discolored; mesentery infiltrated with fecal drainage. One small perforation in transverse colon. Compound fracture, lumbar vertebrae.	Resection of terminal ileum, cecum, ascending colon and proximal transverse colon. Open ends of transverse colon and ileum sutured in approximation, brought out together. Spine through stab wound in right upper quadrant.	Patient died in shock 18 hours after operation. Was in severe shock at end of operation. Necropsy not performed.
1	Ascending colon	Injured about 7-144. A I d i p e r d shock, blood pressure not obtainable.	At least 9	Bullet traversed 9th lumbar vertebra, fractured right iliac crest. Large perforation in posterior aspect of ascending colon. Pyloric mucous process involved. Cancer, ascending colon.	Right colectomy. Mesenteric venostomy; proximal end of colon brought out through stab wound. At end of operation patient's condition very poor.	Patient died 4 hours after operation. Shock, sepsis thought the causes of death.
13	Hepatic flexure	Injured 3-5-145. Wound of back (shell fragment).	13	Fracture 4th lumbar vertebra, contusion right kidney, perforation hepatic flexure of colon, perforation right lobe of liver.	Ascending colon and hepatic flexure mobilized, holes in hepatic flexure closed. Hepatic flexure exteriorized as loop colectomy. Subphrenic space not drained.	Subdiaphragmatic accumulation of bile developed, was drained. Evacuated. 3-16-145.
14	Hepatic flexure	Injured 6-30-145. Penetrating gunshot wound, right chest.	5	Bullet entered hepatic flexure of colon in intraperitoneal part; came out in extraperitoneal part, entered right kidney in upper pole, nicked liver.	Duodenum was mobilized, no omentum found. Hepatic flexure, including omentum, exteriorized.	Evacuated 7-0-145. Report on 8-3-145 Patient doing ill. Colectomy at this time about to be closed.
5	Hepatic flexure	Injured 3-14-145. Small right hemithorax; was aspirated. Paralysis below level of 5th thoracic vertebra.	At least 24	Bone fragments driven into caecum caecum. Right diaphragm, liver retroperitoneal part of hepatic flexure perforated, right kidney severely contused.	Hepatic flexure mobilized, perforations sutured, damaged segment exteriorized as loop colectomy. Bladder was being drained for suprapubic cystostomy, patient suddenly died.	Necropsy: bloody secretions partially obstructing bronchi; telecystic, adenoma of right, left lower lobes, also contusion of right lower lobe.
16	Transverse colon	Injured 2-20-145. Penetrating gunshot wound.	1	Two perforating wounds in jejunum; two in transverse colon.	All four perforations in bowels closed. Perforated area of transverse colon exteriorized.	Evacuated 4-7-145; in good condition.
7	Transverse colon	Injured. 5-10-145. Penetrating gunshot wound, abdomen.	3	Perforation, left part of transverse colon; several tears in jejunum. Right lobe of liver perforated.	Transverse colon exteriorized, jejunum sutured. Liver area drained through right flank wound.	Evacuated 5-4-145; in good condition.
18	Transverse colon	Injured 3-7-145. Grade fragments. Penetrating wound abdomen, small piece extruded herniated through abdominal wound.	4	Perforation transverse colon, ca. diameter. Perforation small, posterior surface stomach, ca. diameter. Laceration ca., tail of pancreas, splenic capsule lacerated, profuse hemorrhage encountered. Retroperitoneal hemorrhage in left kidney region.	Perforations in stomach, colon sutured. Splenectomy. Suture of peritoneum over pancreas. Injured loop of transverse colon exteriorized.	Suture line in colon never broke down 17 days post-operatively exteriorized loop of colon was freed from abdominal wall, repleated in peritoneal cavity. On 3-14-145 patient discharged in excellent condition. Wound completely healed.
19	Transverse colon	Injured 0-7-144. Multiple penetrating small wounds (shell fragments).	13	Two minute perforations, transverse colon. Compound comminuted severe fracture, left humerus, accompanied by left radial nerve injury.	Wounds in transverse colon sutured; colectomy not performed.	Evacuated 10-10-144.
20	Transverse colon	Injured. 4-145. In severe shock. Arrived at scene.	15	Gunshot wound, perforating right chest wall through peritoneal cavity into left rectus muscle in left lower quadrant. Diaphragm lacerated, but pleural cavity not penetrated. Transverse colon perforated twice, jejunum four times, stomach twice. Laceration, laceration of gall bladder; small laceration of liver. Generalized peritonitis. Compound fracture, left femur.	Holes in large bowel, stomach, small bowel sutured, cholecystectomy. Transverse colon exteriorized. Patient never recovered from shock; died 10 hours after operation.	Necropsy: moderate telecystic of lower lobes of both lungs.

RÉSUMÉ 70 CASES OF INJURY TO THE LARGE INTESTINE AUTHORS' SERIES

Case	Part Injured	Clinical history	Hours between injury and operation	Pathologic findings	Operative procedure	Comment
	Cecum	Injured 11-3-1944. Penetrating wound, abdomen (shd fragments).	6	Two small retroperitoneal holes in cecum, spillage in peritoneal cavity.	Cecum mobilized, holes sutured. 2 (1 peritoneal) drains; rubber tube and catheter drain through anterior abdominal wall.	Eviscerated 12-4-1944.
	Cecum	Injured 4-2-1945. Auto accident, thoracic against wheel.	6 1/2	Vertical tear and slight contusion in cecum. First of the colon had small punctate hemorrhages. Cecum had two gangrenous areas at different places, each about 2 in. long. Mesosigmoid had punctate hemorrhages 1,000. Bloody fluid in peritoneal cavity; mild peritonitis with gangrenous areas of gut adherent to adjacent structures.	Double resection of cecum with two end-to-end anastomoses.	Mild bilateral, acute bronchopneumonia. Eviscerated 2-4-45.
2	Cecum	Injured 4-3-1945. Gun shot wound, perforating right flank, compound comminuted fracture of scapula.		Small tear in perforation of right lower quadrant, the small wounds perforating cecum. First wound patent.	Exploration, exploration of wound. 2 (1275 cc) was de co. sutured and closed, loop of cecum preserved.	Cecum wounds sutured separately on end, posterior. Abdomen Eviscerated 1-2-45; good condition.
	Cecum	Injured 10-1945. Compound comminuted fracture of right ilium.	6 1/2	Perforating gunshot wound, exposed entrance in lateral part of right lower quadrant, wound at exit in right buttock. Contusion on dorsum in retroperitoneal part of cecum without perforation.	Treat exposed, wounds debrided. Cecum left in situ; contained area not treated.	Eviscerated 4-10-1945.
5	Ileum	Injured 2-4-1945. Multiple wounds, left forearm, left buttock (shd fragments).	12	Compound comminuted fracture right ilium, with perforation of cecum, transverse colon, lower cecum was entered, long tear extended from cecum into ascending colon.	Right colostomy. Duodenoduodenostomy. Free ends of ileum and colon brought out through buccal stab wound in right upper quadrant.	Eviscerated 2-10-1945. Follow-up note, bowel ends closed off, patient doing well.
6	Ascending colon	Injured 3-16-1945. Penetrating gunshot wound, abdomen. Paralytic both lower limbs. Compound wound (shd) at lumbar 1 with lumbar vertebra.	2-26	Cecum perforated, body of fourth lumbar vertebra perforated. Large laceration through wall of perforating colon at mesenteric border.	Side-to-side duodenoduodenostomy. Cecum, stump of ileum, ascending colon up to perforation exteriorized. Seven day later treatment of peritoneal cavity and lower ascending colon, without anastomosis.	Eviscerated 3-22-1945.
7	Ascending colon	Injured 4-1-1945. Gun shot wound, abdomen.	32	Ascending colon perforated just below hepatic flexure. Laceration of liver, compound comminuted fracture of right ilium.	Cecum, ascending colon, hepatic flexure mobilized, brought on as loop through right subcostal incision. Two holes in colon sutured, loop left suspended.	Seventh, postoperative day patient doing well, colon loop still suspended. Eviscerated 4-2-1945.
8	Ascending colon	Injured 2-5-1944. Gun perforating, two penetrating, gunshot wounds, lower half of back.	12	Small perforation, places of right chest on both sides. Two lacerations of kidney, normal injury to ascending colon, compound comminuted fracture of 1st, 2nd, 3rd lumbar vertebrae and of left and right 11 ribs. Damage to spinal cord.	Resection of right rib, closure of places. Mobilization of ascending colon for inspection. Suture of lacerations of kidney and ascending colon.	Eviscerated 20-7-1944.
	Ascending colon	Injured 10-1945. Severely injured right lateral lumbar region of back (shd fragments).		Retroperitoneal wound, ascending colon draining to back. Wounds, right arm, thigh.	Ascending colon, cecum resected. Ileum sutured to transverse colon; end of transverse colon brought out through right subcostal stab wound.	Jejunostomy, subcutaneous catheter, infection of main abdominal wound. Eviscerated 20-10-1944.
	Ascending colon	Injured 2-1-1945. Wounds, right eye, right arm, right thigh, both legs (shd fragments).	20	Retroperitoneal hemorrhage lateral to ascending colon. Small perforation, middle part of retroperitoneal perforation, ascending colon. Right hip crest fractured.	Ascending colon mobilized. Right ilium sutured, loop colostomy.	Eviscerated: 2-3-1945; bowel suture line still intact.

RÉSUMÉ 70 CASES OF INJURY TO THE LARGE INTESTINE AUTHORS' SERIES

Case	Part Injured	Clinical history	Hours between injury and operation	Pathologic findings	Operative procedure	Comment
	Cecum	Injured 11-12-1944. Penetrating wound, abdomen (shell fragments).	6	Two small retroperitoneal holes in cecum, spillage in peritoneal cavity	Cecum mobilized, holes repaired. R. trepan and drainage rubber tube and cigarette drain through anterior stab wound	Evacuated 14-8-1944.
	Cecum	Injured 4-12-1943. Auto accident, thrown against wheel.	64	Severe tear and slight contusion in cecum. Rest of the colon had small punctate hemorrhages. There had two gangrenous areas at different places, each about 6 in long stomach had punctate hemorrhages 2,500 cc. bloody fluid in peritoneal cavity mild perforation of 1 gangrenous area of gut adherent to adjacent structures	Double resection of ileum with two end-to-end anastomoses.	Mild bilateral, acute bronchopneumonia. Evacuated 1-41
3	Cecum	Injured 4-12-1943. Gun shot wound, perforating right flank, compound comminuted fracture of scapula.	3	Small tear in peritoneum of right lower quadrant (two small wounds perforating cecum). Exit wound para-umbilical	Exploration, exploration of wound. R. trepan and cigarette drain through anterior stab wound.	Cecum wounds opened spontaneously on 3rd postoperative day. Evacuated 3-41 good condition.
	Cecum	Injured 9-4-43. Compound comminuted fracture of right ilium	40	Perforating gunshot wound, wound of entrance in left lateral part of left lower quadrant, wound of exit in right buttock. Communion of cecum on retroperitoneal part of cecum without perforation	Treat exposed, wounds debrided. Cecum left in place, contained area not treated	Evacuated, 4-20-1943.
5	Ileum	Injured 4-4-41. Multiple wounds, left forearm, left buttock (shell fragments)		Compound comminuted fracture right ilium, with perforation of cecum, transverse colon, liver. Cecum was entered, long tear extended from cecum into ascending colon.	Right colectomy. Ileostomy temporary. Free ends of ileum and colon brought out as a loop. Cecum 10 cm. in right upper quadrant.	Evacuated 5-20-1941. Follow-up after bowel closed off, patient doing well.
6	Ascending colon	Injured 5-5-1943. Perforating gunshot wound, abdomen. Paralytic, both lower limbs. Compound comminuted fracture of both tibiae and fibulae.	47-56	Cecum perforated, body of fourth lumbar vertebra perforated. Large laceration through wall of ascending colon 1 cm. anterior border.	End-to-side ileotransversecolostomy. Cecum, stump of ileum, ascending colon up to perforating site exteriorized. Seven days later excision of abdominal cecum and ileum, ascending colon, without anastomosis.	Evacuated 3-23-1943
7	Ascending colon	Injured 8-1-41. Open shot wound, abdomen	3	Ascending colon perforated just below hepatic flexure, laceration of liver; compound comminuted fracture of right ilium	Cecum, ascending colon, hepatic flexure, ligament brought out as loop through right iliac fossa, incision 7 cm. in right anterior, loop still exposed	Small, postoperative days; patient doing well, colon loop still exposed. Evacuated 4-2-1941.
8	Ascending colon	Injured 10-4-41. One perforating, two penetrating, right upper abdomen, lower half of back		Small perforation, pleura of right chest over both ribs. Two lacerations of kidney, second laceration in ascending colon, compound comminuted fracture of 1st, 12th and 13th thoracic vertebrae each of left and right ribs. Damage to spinal cord	Excision of right rib, closure of pleura. Ligation of bleeding colons for inspection. Excision of laceration of kidney and ascending colon	Evacuated, 10-27-1944
	Ascending colon	Injured 9-3-1944. Severe wound, right lateral lower region of back (shell fragments)	21	Retroperitoneal wound; ascending colon dipping to back. R. side right arm, thigh.	Ascending colon, cecum resected. Cecum sutured to transverse colon; end of transverse colon brought out through right iliac fossa stab wound.	Jejunum sutured down, laceration of main abdominal wound. Evacuated 10-23-1944
	Ascending colon	Injured 21-4-41. Wound, right eye, right arm, right thigh, both legs (shell fragments)	20	Retroperitoneal hemorrhage lateral to ascending colon. Small perforation, middle part of retroperitoneal meso-ascending colon. Right iliac crest fractured	Ascending colon mobilized. Right colon sutured, loop colectomy	Evacuated 2-1-1941. Bowel suture line still intact.

RÉSUMÉ 70 CASES OF INJURY TO THE LARGE INTESTINE AUTHORS' SERIES—Continued

Case	Part Injured	Clinical history	Hours between injury and operation	Pathologic findings	Operative procedure	Comment
1	Ascending colon	Injured 11 p 044. Rigid, tender abdomen, complete paralysis right lower extremity, partial paralysis of left.	4	Perforating wound abdomen (shell fragment). Peritoneal cavity filled with much dirty focal-coagling bloody fluid, generalized peritonitis present. Ascending colon perforated twice, was dark, discolored, mesentery infiltrated with focal drainage. One small perforation in transverse colon. Compound fracture, lumbar vertebra.	Resection of terminal ileum, cecum, ascending colon and proximal transverse colon. Open ends of transverse colon and ileum sutured in approximation brought out together as spig through stab wound in right upper quadrant.	Patient died in shock 8 hours after operation. Was in severe shock at end of operation. Necropsy not performed but death thought to be due to peritonitis and shock.
	Ascending colon	Injured about 11 p 044. A shell fragment in right chest, blood pressure not obtainable.	At least 9	Bullet traversed 5th lumbar vertebra, fractured right iliac crest. Large perforation in posterior aspect of ascending colon. Phlegmonous process involved cecum ascending colon.	Right colectomy. Ileotransverse anastomosis; proximal end of colon brought out through stab wound. At end of operation, patient's condition very poor.	Patient died 14 hours after operation. Shock, sepsis thought the causes of death.
23	Hepatic flexure	Injured 3-5-045. Wound at back (shell fragment).	3	Fracture 4th lumbar vertebra, condition risk to life. Perforation hepatic flexure of colon, perforation right lobe of liver.	Ascending colon and hepatic flexure mobilized; holes in hepatic flexure closed. If hepatic flexure exteriorized as loop colostomy. Subphrenic space not drained.	Subdiaphragmatic accumulation of bile developed, was drained. Evacuated 3-10-045.
24	Hepatic flexure	Injured 6-30-045. Penetrating gunshot wound, right chest.	5	Bullet entered hepatic flexure of colon in its intraperitoneal part; entered right kidney in upper pole, nicked liver.	Doodson was mobilized, no wound found. Hepatic flexure including wounded segment, exteriorized.	Evacuated 7-10-045. Report on 8-3-045 Patient doing well. Colostomy at this time about to be closed.
5	Hepatic flexure	Injured 8-24-045. Small right beneath ribs; this was aspirated. Sensory paralysis below level of 12th thoracic vertebra.	At least 24	Bone fragments driven into parietal cavity. Displacement, liver retroperitoneal part of hepatic flexure perforated; right kidney severely contused.	Hepatic flexure mobilized; parietal cavity drained; segment exteriorized as loop colostomy. While bladder was being distended for suprapubic cystostomy patient suddenly died.	Necropsy: bloody secretions partially obstructing bronchi arteriosclerosis, edema of right, left lower lobes, also contusion of right lower lobe.
6	Transverse colon	Injured 4-30-045. Penetrating gunshot wound.		Two perforating wounds in jejunum, two in transverse colon.	All four perforations in bow closed. Perforated area of transverse colon exteriorized.	Evacuated 4-7-045 in good condition.
27	Transverse colon	Injured 9-045. Penetrating gunshot wound, abdomen.	5	Perforation, left part of transverse colon across near jejunum. Right lobe of liver perforated.	Transverse colon exteriorized, 1 loop sutured. Liver area drained through right flank wound.	Evacuated 9-24-045 in good condition.
8	Transverse colon	Injured 3-7-045. One shell fragment. Penetrating wound abdomen, small pleural secretions extravasated through abdominal wound.	4	Perforations transverse colon, cm. diameter. Perforation stomach, posterior surface stomach, cm. diameter. Laceration cm. tail of pancreas. Splenic vein lacerated; profuse hemorrhage encountered. Retroperitoneal hemorrhage in left kidney region.	Perforations in stomach, colon sutured. Splenectomy. Sutures of peritoneum over pancreas. Injured loop of transverse colon exteriorized.	Suture line in colon never broke down 17 days post-operatively exteriorized loop of colon was freed from abdominal wall, replaced in peritoneal cavity. On 7-045 patient discharged in good condition. All wounds completely healed.
10	Transverse colon	Injured 10-7-044. Multiple penetrating small wounds (shell fragments).	23	Two minute perforations, transverse colon. Compound comminuted severe fracture, left femur, accompanied by left radial nerve injury.	Wounds in transverse colon sutured; colostomy not performed.	Evacuated 10-20-044.
30	Transverse colon	Injured 4-045 in severe shock on arrival. Ch at wound in abdomen.	5	Gunshot wound, perforating right chest wall through peritoneal cavity into left rectus muscle in left lower quadrant. Diaphragm lacerated, but paravertebral cavity not penetrated. Transverse colon perforated twice; jejunum four times, stomach twice. Laceration, lumen of gall bladder; small laceration of liver. Generalized peritonitis. Compound fracture left femur.	Holes in large bowel, stomach, small bowel sutured, cholecystectomy. Transverse colon exteriorized. Patient never recovered from shock; died 30 hours after operation.	Necropsy: moderate atelectasis of lower lobes of both lungs.

RESUME 70 CASES OF INJURY TO THE LARGE INTESTINE AUTHORS' SERIES—Continued

Case	Part Injured	Clinical History	Hours between injury and operation	Pathologic findings	Operative procedure	Comment
	Splenic flexure	Injured 10-17-1944. Two penetrating wounds, left lateral chest wall (shell fragments).	30	Mesenter had entered pleural cavity; several small perforations in diaphragm; perforation splenic flexure of colon in four places. Spleen lacerated.	Thoracotomy; three closures of diaphragm. Next, exploratory celiotomy. Hole in splenic flexure sutured. Transverse loop colostomy. Splenectomy.	Evacuated good condition. #441 in
21	Splenic flexure	Injured 3-3-1944. Penetrating wound, abdomen (shell fragment).	1	Splenic flexure of colon completely divided. Small bowels completely destroyed in places.	Splenic flexure mobilized. Mitikka double-barrelled colostomy performed. Four feet of jejunum resected.	Evacuated 1-3-44 in excellent condition.
22	Splenic flexure	Injured 1-3-44. Penetrating wound of back (shell fragment).		Spleen lacerated, pancreas lacerated, splenic flexure perforated in two places.	Splenectomy. Perforations in colon sutured. Transverse colostomy. On 4-10-44 small loop of small intestine was prepared through wound. Wound sutured. On 2-3-44, after 10 days of obstruction, operation was performed which showed intussusception of 30 inches of small intestine protruding at terminal part of ileum. Intussusception was freed and reduced.	Evacuated 2-4-44, doing well.
24	Splenic flexure	Injured 2-6-44.	14	Large defect in left upper quadrant. Splenic flexure of colon and jejunum in two areas contused, without loss of vitality.	Celiotomy. Colostomy not done.	Moderate atelectasis of both lungs developed. Evacuated 2-27-44.
25	Splenic flexure	Injured 10-17-1944.	8	One small perforation distal, one proximal, to splenic flexure. Several transverse colon.	Recess of two wounds in colon; transverse colostomy.	Massive colectomia developed, but general condition of patient good. Evacuated 1-3-44.
26	Splenic flexure	Exact time of wounding not known. In severe shock on admission; cyanotic, with large hemothorax on left.	At least 21	Fracture of left transverse by severe penetrating gunshot wound. Bullet then entered left flank, lacerated left lower lobe of lung, left diaphragm, spleen, splenic flexure of colon, left kidney, liver. Perforation in splenic flexure 1 cm long. Large hemoperitoneum (large, left retroperitoneal hematoma).	Splenectomy; diaphragm sutured. Splenic flexure partially mobilized, hole in it sutured. Loop of transverse colon brought out through abdominal incision as colostomy.	Patient died hours after operation, never recovering from shock. During this time only 120 cc. of urine was secreted. Autopsy severe pulmonary infarction. Pyonephrotic cysts demonstrated in kidneys.
27	Splenic flexure	Injured 11-4-44.		Hemoperitoneum (due with two perforations of splenic flexure of colon, one of small bowel). Kidney lacerated.	Perforation in small bowel closed, splenic flexure mobilized, injured segment in colon sutured, the small left abdominal stab wound as loop colostomy. As abdomen was being closed, intravascular blood and heart stopped, patient died.	Autopsy early mild hemorrhagic pneumonia. Death due to shock, pneumonia.
28	Splenic flexure	Injured 11-2-44. Admitted in severe shock. It was thought there was hemorrhage because of patient's dermal (all) course in spite of transfusion, so transfusion resumed, patient in operating room, changing transverse operation was performed only loops. Large left operation in patient's general shock condition was hopeless, advised continued home therapy. Death occurred 6 hours after wounding.		Peritoneal cavity contained local matter much blood. Large perforations in jejunum, splenic flexure of colon, descending colon. Kidney contused.		Autopsy
29	Splenic flexure	Injured 11-19-1944.		Five perforations, each about 6 mm diameter in splenic flexure, laceration of spleen.	Wounds in colon placed; splenic flexure mobilized. During splenectomy several anastomoses from the splenic vessels encountered. Patient went into severe shock. Loop colostomy brought out in lateral angle of transverse incision, all placed wounds of splenic flexure externalized.	Celiotomy opened on the second postoperative day. Large to fistulae well. Patient died on seventh postoperative day. Autopsy showed anemia, moderate edema, in left quadrant of abdomen; tubular pneumonia; moderate edema of brain.

RÉSUMÉ 70 CASES OF INJURY TO THE LARGE INTESTINE AUTHORS' SERIES—Continued

Case	Part Injured	Clinical history	Hours between injury and operation	Pathologic findings	Operative procedure	Comment
30	Descending colon	Injured 9-7-04. Admitted to hospital 9-8-04. Perforating gunshot wound one wound in left flank one in right flank posteriorly; 3rd lumbar vertebra compound comminuted fracture severe cord damage.		Severe perforating wound, descending colon; left kidney moderately severely lacerated.	Wound of left colon exteriorized; suprapubic cystostomy done several days later.	9-12-04, severe meningitis developed, cleared up. Paralysis of lower extremities incomplete. Evacuated 9-04.
31	Descending colon	Injured 4-30-045	16	Multiple holes, descending colon, middle third. Loop of jejunum almost completely transected in two places; other holes present.	Five inches jejunum resected; end-to-end anastomosis performed. Splenic flexure mobilized; damaged segment of descending colon exteriorized.	Evacuated 4-30-045 doing well.
32	Descending colon	Injured 4-30-045. Tag of jejunum hit through entrance wound.	30	Three moderately large perforations, descending colon. Retroperitoneal tissues very dirty; lower pole of kidney knocked off.	Descending colon mobilized, perforations sutured, damaged part exteriorized.	Evacuated 9-2-045; in good condition.
33	Descending colon	Injured 4-2-045	23	Wound tract soiled, suppurated a thro' gbo t. Descending colon almost completely transected at junction with splenic flexure. Qc ral and perit. nitric thick fibrous coating over contents of left upper quadrant, most of small bowel.	Descending colon, distal part of splenic flexure mobilized, division of flexure completed. P im l d i l n brought out through subcostal stab wound; distal end through extraperitoneal in back. During procedure patient went into shock.	Evacuated 5-045; doing well.
34	Descending colon	Injured 11-045. Missle probably perforated abdomen, came out through wound in left upper quadrant just below costal margin, int. which loop of large bowel had herniated. General condition good.	20	Two perforations in descending colon on middle part was extraperitoneal other was 7 cm. distal.	Descending colon mobilized, injured part exteriorized through left McBurney incision.	Evacuated 2-4-045 in good condition.
35	Descending colon	Injured 4-2-045. Admitted in profound shock. P f rat l s g u k t wound, abdomen, small entrance wound in right upper quadrant. Exit wound, 3 cm. diameter, in left flank, from which 3 feet of jejunum, with four perforations in it, were herniated. Believed evicoration would help patient's general status, he was transferred to operating room. Perforations in jejunum sutured, then patient anesthetized with nitrous oxide-oxygen anesthesia for few minutes; bowel reduced. Cabot only 18 hours after wound-lag; two hours after reduction of jejunum.	8	Two small perforations in transverse colon; 4 cm. perforation in descending colon. Moderate laceration, left kidney.	Descending colon wound exteriorized. Suture of transverse colon perforations. At end of operation patient in severe shock.	Patient did not recover from shock; died 8 hours postoperatively. Autopsy nothing additional.
36	Descending colon	Injured 4-10-045. Admitted severe shock; dyspneic, pale cyanotic. Recurrent tension pneumothorax, for which thoracotomy done. Perforating wound of left pleural cavity. Paralysis both lower extremities. Fecal drainage from left fl k w d Shock treated with 500 cc. plasma oo wh l blood.	5	Massive retroperitoneal hematoma extending down into pelvis from left upper quadrant. No intraperitoneal perforation of colon. Was removed from fecal drainage from wound, tract of missile, and clinical and operative finding that there was perforating wound of retroperitoneal descending colon.	Left upper quadrant, flank, quickly explored through left paramedian incision. Patient went into profound shock, so abdomen was closed with loop of transverse colon, exteriorized. Death ensued few moments later.	No autopsy. Cause of death believed to be traumatic, operative shock.

RÉSUMÉ. 70 CASES OF INJURY TO THE LARGE INTESTINE. AUTHORS' SERIES—Continued

Case	Part injured	Clinical history	Hours between injury and operation	Pathologic findings	Operative procedure	Comment
22	Splenic flexure	Injured 10-12-1944. Two penetrating wounds, left lateral chest wall (shell fragments).	20	Mesenter had severed splenic artery; several small perforations in diaphragm; perforation splenic flexure of colon in four places. Spleen lacerated.	Thoracotomy; then closure of diaphragm. Next, exploratory laparotomy. Spleen in splenic flexure sutured. Transverse loop colostomy. Ileostomy.	Evacuated good condition. 9-4-45
23	Splenic flexure	Injured 7-3-1944. Penetrating wound, abdomen (shell fragment).	5	Splenic flexure of colon completely divided. Small loop of jejunum destroyed in places.	Splenic flexure mobilized. Jejunum double-barrelled colostomy performed. Four feet of jejunum resected.	Evacuated 1-4-45 9-4-45 in excellent condition.
24	Splenic flexure	Injured 1-12-1944. Penetrating wound of back (shell fragment).	12	Spleen lacerated, pancreas lacerated, splenic flexure perforated in two places.	Thoracotomy. Splenic flexure in colon sutured. Transverse colostomy. On 7-4-45 small loop of small intestine protruded through wound. Wound resected. On 8-4-45, after 30 days of observation, operation was performed which showed no interruption of jejunum or small intestine. Spleen and ventral part of duodenum in transverse colon was freed and resected.	Evacuated. 2-9-1945 doing well.
25	Splenic flexure	Injured 5-12-1944	14	Large defect by left posterior splenic flexure of colon and jejunum in jejunum continued, with loss of vitality.	Colostomy. Colostomy performed.	Moderate atelectasis of both lungs developed. Evacuated 2-27-1945.
26	Splenic flexure	Injured 10-7-1944	8	One small perforation duodenum proximal, to splenic flexure, duodenum transverse colon.	Seton of two wounds in colon, transverse colostomy.	Moderate infections developed, but general condition of patient good. Evacuated 12-4-45.
27	Splenic flexure	Exact time of wounding not known. In severe shock on admission; cyanosis, with large hemorrhoids on left.	At least 22	Fracture of left kidney by severe penetrating gunshot wound. Bullet then entered left scilla, lacerated left lower lobe of lung, left diaphragm, spleen, splenic flexure of colon, left kidney, liver. Perforation in splenic flexure 3 cm loop. Large hemorrhagic area, large left retroperitoneal hemorrhage.	Exploratory laparotomy performed. Splenic flexure partially mobilized; hole in it repaired. Loop of transverse colon lacerated, cut through abdominal incision to colostomy.	Patient died 1 month after operation, never recovering from shock. During this time only 5 cc. of urine voided. Autopsy: severe pulmonary but no infection. Fragmented chest demonstrated in kidneys.
28	Splenic flexure	Injured 10-9-44		Hemoperitoneum (also with two perforations in splenic flexure of colon, one of small bowel. Kidney lacerated).	Perforation in small bowel closed; splenic flexure mobilized, injured segment of colon exteriorized through left abdominal stab wound as loop colostomy. As abdomen was being closed, rupture torn and heart stopped, patient died.	Autopsy: early acidosis; shock; peritonitis. Death due to shock, peritonitis.
29	Splenic flexure	Injured 2-14-1944. Admitted in severe shock 5 1/2 hours after thought there was hemorrhage because of patient's decreased consciousness on spite of transfusion, so left transfused patient in operating room, thinking immediately operation was patient's only hope. Surgery left operation in patient's present shock condition was hopeless; advised continued passive therapy. Death occurred 16 hours after wounding.		Peritoneal cavity contained small section small blood. Large perforation in jejunum, splenic flexure of colon, descending colon. Kidney contained.	Anteapex	Anteapex
30	Splenic flexure	Injured 10-9-44		Five perforations, each about 4 mm diameter in splenic flexure laceration of spleen.	Wound in colon placed; splenic flexure mobilized. During operation severe hemorrhage from the splenic vessels encountered, but blood went to severe shock. Loop colostomy brought out in lateral angle of transverse incision, all places and wounds of splenic flexure exteriorized.	Colostomy opened on the second postoperative day began to function well. Patient died on seventh postoperative day. Autopsy showed shock, moderate necrosis in left quadrant of diaphragm; jejunum contained moderate edema of lumen.

RÉSUMÉ 70 CASES OF INJURY TO THE LARGE INTESTINE AUTHORS' SERIES—Continued

Case	Part Injured	Clinical history	Hours between injury and operation	Pathologic findings	Operative procedure	Comment
30	Descending colon	Injured 9-7-944. Admitted to hospital 9-8-944. Perforating gunshot wound, one wound in left flank; one in right flank posteriorly; and lumbar vertebra compound comminuted fracture severe cord damage.		Severe perforating wound, descending colon, left kidney moderately severely lacerated.	Wound of left colon exteriorized, suprapubic cystostomy done several days later.	9-8-1944 severe meninges developed; cleared up. Paralysis of lower extremities incomplete. Evacuated, 9-21-1944.
31	Descending colon	Injured 4-30-945	6	Multiple holes, descending colon, middle third. Loop of jejunum almost completely transected in two places; other holes present.	Five inches jejunum resected; end-to-end anastomosis performed. Splenic flexure mobilized, damaged segment of descending colon exteriorized.	Evacuated, 4-30-1945 doing well.
32	Descending colon	Injured 4-30-945 Tag of intestine through entrance wound	30	Three moderately large perforations, descending colon. Retroperitoneal tissues very dirty; lower pole of kidney knocked off.	Descending colon mobilized; perforations sutured; damaged part exteriorized.	Evacuated, 5-15-1945 in good condition.
33	Descending colon	Injured 4-22-945.	23	Wound tract soiled, suppurative thro' abs. Descending colon almost completely transected at junction with splenic flexure. O. or mixed peritonitis, thick fibrinous coating over contents of left upper quadrant, most of small bowel.	Descending colon, distal part of splenic flexure mobilized, division of bow. completed. P. in l. and r. less brought out through subcostal stab wound, distal end through entrance wound in back. During procedure patient went into shock.	Evacuated, 5-1945; doing well.
34	Descending colon	Injured 4-23-945. Missile probably perforated abdomen, came out through wound in left upper quadrant just below costal margin, to which loop of large bowel had herniated. General condition good.	25	Two perforations in descending colon, one in middle part was extraperitoneal other was 7 cm. distal.	Descending colon mobilized, injured part sutured through left McBurney incision.	Evacuated, 5-4-1945; in good condition.
35	Descending colon	Injured 4-3-945. Admitted in profound shock. Perforating gunshot wound, abdomen small entrance wound in right upper quadrant. Exit wound, 3 cm. diameter in left flank, from which 3 feet of jejunum, with four perforations in it, were herniated. Believed ventilation would help patient's general status he was transferred to operating room. Perforations in jejunum sutured, then patient anesthetized with nitrous oxide-oxygen anesthesia for few minutes, bowel reduced. Colotomy 8 hours after wounding; two hours after reduction of jejunum.	18	Two small perforations in transverse colon 4 cm. perforation in descending colon. Moderate laceration, left kidney.	Descending colon mobilized, transverse colon perforation exteriorized. Bottom of transverse colon peristalsis at end of operation present in severe shock.	Patient did not recover from shock; died 8 hours postoperatively. Autopsy: nothing additional.
36	Descending colon	Injured 8-10-944. Admitted in severe shock; dyspnoic, pale, cyanotic. Recurrent tension pneumothorax, for which two thoracotomy done. Perforating wound of left pleural cavity. Paralysis both lower extremities. Fecal drainage from left iliac wound. Shock treated with 500 cc. plasma.	5	Massive retroperitoneal hematoma extending down into pelvis from left upper quadrant. No intraperitoneal perforation of colon. Was assumed, from fecal drainage from wound, tract of missile, and clinical and operative finding that there was perforating wound of retroperitoneal descending colon.	Left upper quadrant quickly explored. Left paramedian incision. Patient went into shock, so abdomen closed with loop suture colon. Death ensued a moments later.	Causes of death assumed to be traumatic. No severe shock.

RÉSUMÉ. 70 CASES OF INJURY TO THE LARGE INTESTINE. AUTHORS' SERIES—Continued

Case	Part injured	Clinical history	Hours between injury and operation	Pathologic findings	Operative procedure	Comment
37	Descending colon	Injured 8-31-34. One small wound in right buttock over sig. of caecum (groove of inguinal).	29	Each wound tract led through compound fracture in corresponding ilium. Retroperitoneal perforation in both caecum and descending colon. Retroperitoneal abscesses had developed behind and lateral to tear in descending colon. No peritonitis or contamination of the peritoneal cavity. Two abscesses were first opened. Later severe spillage of abscess contents, with spread of feces and pus into peritoneal cavity.	Performed cecum mobilization, exteriorized through right iliofemoral incision. Descending colon mobilized, wounded segment exteriorized. During procedure patient went into profound shock and died.	Autopsy: small number of perforations in capsule of peritoneum. No evidence of fatal dam. Cause of death shock.
38	Sigmoid colon	Injured 8-2-34. Multiple penetrating wounds, buttocks, abdomen (left) (superior). Penetrating wound of left pop. rt. chest. Hemiparalysis of right present.	84	Multiple entered left chest, lacerated lower lobe left lung, perforated the pleural cavity, perforated stomach in two places. Three perforations in sigmoid colon.	Incision in sigmoid colon placed, injured loop exteriorized. Flaps in the same sutured.	Postoperative course very satisfactory; development of post-operative abscesses. Report type of (temperature) very low; patient became extremely ill. After sudden appearance of massive, foul-smelling feces from colostomy lower sutured. Examined 8-20-34 still sick.
39	Sigmoid colon	Injured 8-10-34. Penetrating wound, abdomen, from which a piece of small bowel protruded. Severe shock.	7	Two small perforations in transverse colon, one perforation in sigmoid, the diameter smaller than plumb. Sigmoid, a large laceration in area of a foot.	Colon perforations exteriorized, transverse colostomy brought on in right upper quadrant, 3 feet of jejunum resected, side-to-side anastomosis done.	Excavated abscess in day postoperatively; doing ill.
40	Sigmoid colon	Injured 8-10-34. One shot, apex of abdomen, from which compound lacerated.	3 1/2	Large hemiparalysis. Five perforations of jejunum. Two perforations of liver, laceration of mesogastrium, contusion of sigmoid colon. Early peritonitis.	Twelve inches of jejunum resected, perforation in liver exteriorized, contained sigmoid exteriorized.	Injured colon resected in situ. Obstruction of small bowel developed, caused by adhesions, which were divided. Internal operation. Excavation 8-20-34.
41	Sigmoid colon	Injured 8-10-34.	36	Perforation, sigmoid colon, right lobe of liver perforated.	Perforation of sigmoid colon closed, brought out in loop colostomy.	Evacuated 8-20-34. It which (two sigmoid perforations) had not responded.
42	Sigmoid colon	Injured 8-10-34.	1	Gravel wound in sigmoid colon without perforation. Wound 1 cm diameter, penetrated into musculature.	Sigmoid wound exteriorized.	Abdominal distention developed which necessitated opening of colostomy. Examined 8-20-34.
43	Sigmoid colon	Injured 8-10-34.	5	Penetrating wound, junction of descending colon, sigmoid. Small perforating wound (average 1 cm) on posterior surface. One perforation found in terminal ileum.	Perforation in colon exteriorized, descending colon, sigmoid mobilized, exteriorized. Perforation in ileum closed. Cecum exteriorized.	Patient died, with postoperative day. Autopsy: severe generalized peritonitis.
44	Sigmoid colon	Injured 8-10-34.	70	One perforation of sigmoid colon, three perforations of small bow. Compound fracture, humeral; removal of left pelvis and left tibia; colostomy.	Perforations in small bowel exteriorized. Left sigmoid loop colostomy.	Patient, 31 and of procedure in profound shock from which he never recovered.
45	Sigmoid colon	Injured 8-12-34. Admitted 8 hours after injury. Abdominal distention, wound in sigmoid; feces extruding from it. Patient almost dead from shock. Systolic blood pressure up to 100 mm. (radial) pulse barely palpable for short period. Died 12 hours after admission.				Autopsy: generalized peritonitis, from fecal contamination. A severe hemiparalysis. Three perforations in sigmoid colon, each about 2 cm. diameter. Perforation of ileum, of jejunum.
46	Sigmoid colon	Injured 8-10-34.	33	Compound fracture, coccyx, extensive retroperitoneal lacerations in pelvis. Rectum and sigmoid colon perforated. Laceration of sigmoid (transverse) two small perforations in small bowel.	A track wound extended coccyx outward. All wounds of bowel exteriorized. Left lower quadrant loop colostomy performed.	Evacuated abscess in day postoperative. 8-20-34.

RÉSUMÉ 70 CASES OF INJURY TO THE LARGE INTESTINE AUTHORS SERIES—Continued

Case	Part injured	Clinical history	Hours between injury and operation	Pathologic findings	Operative procedure	Comment
47	Rectum	Injured 8-30-044. Compound comminuted complete fractures, both ischuria, left pubic bone.	At least 4	Focal abscess between bladder and left pubic bone. Upper urethra and rectum below peritoneal reflection were perforated.	Suprapubic cystostomy; fecal abscess drained. Sigmoid loop colostomy. Debridement of other wounds.	Evacuated 9-3-044 postillid 11 g f m bsc cavity
48	Rectum	Injured 10-13-1944.		Large extraperitoneal tear of rectum, into prostate; extensive retroperitoneal hemorrhage in pelvis.	Buttock wound debrided down to rectum; drainage established. Sigmoid colostomy. Suprapubic cystostomy.	Minute perforating wound of bladder, displaced ure, discovered by cystoscopy. Evacuated 3-044 in good condition.
49	Rectum	Injured 2-14-044.	25	Rectum comminuted with both left buttock wound and extraperitoneal perforation of bladder. Intraperitoneal perforation of bladder. Left pneumothorax; perforated diaphragm; stellate fracture of spleen. Large hemoperitoneum.	Sigmoid colostomy. Intraperitoneal perforation of bladder sutured. Splenectomy. Suprapubic cystostomy. Left chest aspirated.	Evacuated 27-10-44. On 7th day postoperatively, cystoscopy disclosed that rectovesical fistula had become closed. On 3-28-044 patient's general condition was good.
50	Rectum	Injured 4-8-045. Compound comminuted fractures, right ischial tuberosity, left pubic bone.	23	Stellate perforation involving the anterior and lateral wall, lower rectum anal. Urethra lacerated.	All wounds debrided. Laceration of membranes repaired, suprapubic cystostomy. Sigmoid loop colostomy.	Evacuated 4-8-045; doing well.
51	Rectum	Injured 4-24-045.	18	Perforating wound, anterior wall of rectum, posterior aspect right lateral lobe of prostate with compound comminuted fracture of ischium.	N. Intra-abdominal injury. Exploratory cystostomy. Suprapubic catheter inserted. Buttock wound debrided; drainage established down to rectum. Sigmoid loop colostomy.	Evacuated 4-28-1945; doing well.
52	Rectum	Injured 4-3-045. Perforation of bladder, abdominal. Small bowel herniated through exit wound.	20	Wound tract led through perforation right lateral wall of rectum to extraperitoneal portion into bladder, which had intraperitoneal perforation 5 inches long. Three feet of ileum had multiple perforations, one transection. Extensive peritonitis.	Resection, 3 1/2 feet ileum. Bladder sutured. Suprapubic cystostomy. Sigmoid loop colostomy. Buttock wound debrided down to rectal wound.	Evacuated 5-8-045; doing well.
53	Rectum	Injured 4-26-1945	4	Perforation intraperitoneal portion of rectum, much gross fecal soiling; generalized peritonitis.	Rectum sutured. Sigmoid loop colostomy. Buttock wound debrided.	Fourth day postoperatively: cystoscopy of rectovesical fistula. Suprapubic cystostomy. Evacuated 5-4-045 in good condition.
54	Rectum	Injured 8-30-044. Operation 8-3-044.	3	Laceration, lower part of rectum.	Loop sigmoid colostomy. Buttock wound debrided down to rectum.	Patient had low-grade fever. Evacuated 9-4-044.
55	Rectum	Injured 7-29-044.	Probably 24	Small hemorrhage in marked retroperitoneal hemorrhage. Severe perforation, extraperitoneal rectum.	Exploratory cystostomy. Buttock wound only partially debrided because of severe shock. Sigmoid loop colostomy.	After 30 hours, further debridement of buttocks, coccygectomy carried out. Evacuated 9-3-044 doing well.
56	Rectum	Injured 9-4-044. Opened wound left buttock; severe compound comminuted fracture ilium.	26	Severe perforation, extraperitoneal portion of rectum.	Buttock wound debrided. Coccygectomy. Sigmoid colostomy.	Evacuated 6th day postoperatively.
57	Rectum	Injured 9-29-1944.	26	Wound 6 cm. in diameter right buttock; feces contained with hole, 1 cm. in diameter in posterior wall of extraperitoneal part of rectum.	Buttock wound debrided. Exploratory colostomy. Loop sigmoid colostomy.	After about 6 months, the colonic stoma still in sec. Coccyx had been resected; buttock wound was still draining.
58	Rectum	Injured 3-5-044.	10	Fracture coccyx as seen right ischium; moderately large perforation, on posterior aspect of rectum.	Buttock wound debrided. Coccygectomy. Sigmoid colostomy.	Evacuated 3-045.
59	Rectum	Injured 20-045.	13	One perforation of rectum in junction with vesical fold of peritoneum. Two other perforations 4 inches higher up in rectovesical cul-de-sac.	All three perforations in bowel closed. Sigmoid loop colostomy.	Unfavorable course. Evacuated 2-1-1945.

RÉSUMÉ 70 CASES OF INJURY TO THE LARGE INTESTINE AUTHORS' SERIES—Continued

Case	Part Injured	Clinical history	Hours bet. injury and operation	Pathologic findings	Operative procedure	Comment
47	Rectum	Injured. 8-29-044. Compound comminuted compound fracture, both femurs, left pubic bone.	At least 24	Fecal abscess between bladder and left pubic bone. Ureter urethra and rectum below peritoneal reflection were perforated.	Suprapubic cystostomy; fecal abscess drained; sigmoid loop lost my débridement of othe wounds.	Evacuated. 9-3-044; poss still d. g l m bones cavity
48	Rectum	Injured. 10-3-044.	20	Large extraperitoneal tear of rectum, into prostate; extensive retroperitoneal hemorrhage to pelvis.	B. stock w. d débrided down t rectum drainage established. Sigmoid colostomy suprapubic cystostomy	Mia is perforating wound of bladder pinpoint size disc. d by cyst copy. Evacuated. 7-3-044 in good condition.
49	Rectum	Injured. 14-044.	15	Rectum communicated with both left buttock wound and extraperitoneal perforation of bladder. Intraperitoneal perforation of bladder. Left pneumothorax, perforated diaphragm, sternal fracture of plectra. Large hemoperitoneum.	Sigmoid colostomy. Intraperitoneal perforation of bladder sutured. Splenectomy. Suprapubic cystostomy. Left chest aspirated.	Evacuated. 1-27-044. On 7th day postoperatively cystoscopy disclosed that rectovesical fistula had become closed. On 3-16-044 patient's general condition was good.
50	Rectum	Injured. 4-8-043. Compound comminuted fractures, right ischial tuberosity left pubic bone.	23	St. Harts perforation involving the anterior and lateral wall, lower rectum, anus. Urethra lacerated.	All wounds débrided. Laceration of membranes urethra repaired, suprapubic cystostomy. Sigmoid loop colostomy.	Evacuated. 4-5-043 doing well.
51	Rectum	Injured. 4-24-045.	8	Perforating wound, anterior wall of rectum, posterior aspect right lateral lobe of prostate with compound comminuted fracture of ischium.	1. Intra-abdominal injury. Exploratory cystostomy. Suprapubic catheter inserted. B. stock wound débrided, drainage established down to rectum. Sigmoid loop colostomy.	Evacuated. 4-29-045 doing well.
52	Rectum	Injured. 4-3-045. Perforating wound, abdomen. Small bowel herniated through exit wound.	20	Wound tract led through perforation right lateral wall of rectum to extraperitoneal portion into bladder which had intraperitoneal perforation 5 inches long. Three feet of ileum had multiple perforations, one transection. Extensive peritonitis.	Resection, 15 feet ileum. Bladder sutured. Suprapubic cystostomy. Sigmoid loop colostomy. Bladder wound débrided down t rectal wound.	Evacuated. 5-2-045 doing well.
53	Rectum	Injured. 4-26-1943.	14	Perforation intraperitoneal portion of rectum much gross fecal soiling; generalized peritonitis.	Rectum sutured. Sigmoid loop colostomy. Bladder wound débrided.	Fourth day postoperatively cystoscopy of rectovesical fistula. Suprapubic cystostomy. Evacuated 5-4-043 in good condition.
54	Rectum	Injured. 8-20-045. Operation 8-31-044.	3	Laceration, lower part of rectum.	Loop sigmoid colostomy. B. stock wound débrided down t rectum.	Patient had low-grade fever. Evacuated 9-4-1944.
55	Rectum	Injured. 7-20-1944.	Probably 24	Small hole in peritoneum marked retroperitoneal hemorrhage. Severe perforation, extraperitoneal rectum.	Exploratory celiotomy. B. stock wound only partially débrided because of severe shock. Sigmoid loop colostomy.	After 30 hours, further débridement of buttocks, coccygectomy my rectal fistula. Evacuated. 9-3-1944; doing well.
56	Rectum	Injured. 9-4-044. Gunshot wound left buttock severe compound comminuted fracture ilium.	26	Severe perforation, extraperitoneal portion of rectum.	B. stock wound débrided. Coccygectomy my Sigmoid colostomy.	Evacuated 6th day postoperatively.
57	Rectum	Injured. 9-20-1944.	26	Wound 6 cm. diameter in right buttock wound débrided with hole 2 cm. diameter posterior wall of extraperitoneal part of rectum.	B. stock wound débrided. Exploratory celiotomy. Loop sigmoid colostomy.	After about 6 months, the colostomy stoma still in use. Coccyx had been resected, buttock wound was still draining.
58	Rectum	Injured. 11-03-1944.	1	Transverse abscess from right ischium associated by large perforating wound, posterior aspect of rectum.	B. stock wound débrided. Coccygectomy my Sigmoid colostomy.	Evacuated. 045.
59	Rectum	Injured. 10-045.	1	One perforation of rectum, 3 inches with wound fistula of peritonitis. Two other perforations, 1 inch 1/2 inch 1/2 inch rectum and colon.	All three perforations in lower rectum. Sigmoid loop colostomy.	Ureteral catheter abscess. Evacuated 11-045.

RÉSUMÉ. 70 CASES OF INJURY TO THE LARGE INTESTINE AUTHORS' SERIES—Continued

Case	Part Injured	Clinical History	Hours between Injury and operation	Pathologic Findings	Operative procedure	Comment
50	Rectum	Injured 2-8-1945. Opened from 4-4 PM 9:45 AM		Fracture, coccyx perforation on 10 diameter extraperitoneal rectum.	Sigmoid loop colostomy. Distal wound debrided. Cecostomy.	Evacuated 2-8-1945; doing well.
51	Rectum	Injured 2-26-1945.	11	Perforation, on diameter, rectum, just above anus.	Distal loop colostomy. Sigmoid loop colostomy.	Evacuated 2-27-1945; 1 good condition.
52	Rectum	Injured 2-2-1945. Fracture, coccyx.	15	Perforation, anterior passage into wall, extraperitoneal part of rectum.	Cecostomy. Sigmoid loop colostomy. Distal wound debrided; retrorectal incision drained.	Periprosthetic colostomy retracted because patient was almost healed; released 6-2-1945; in good condition.
53	Rectum	Injured 4-11-1945. Perforation, gunshot wound opened left buttock, exit via left groin.	4	Compound comminuted fracture, coccyx, fracture, ilio-lumbar forage body found in sacral of rectal wall, but perforation into lumen of rectum not proved.	Sigmoidectomy. Sigmoid loop colostomy.	Evacuated 4-12-1945. On 2-2-1946, buttock wound was almost healed; release notes still in use.
54	Rectum	Injured 2-7-1945.	14	Sigmoidectomy showed moderate amount of fresh blood coming from perforated colon, but no hole seen in wall of colon. Extraperitoneal hemorrhage along anterior wall of rectum and retroperitoneal colon. Compound comminuted fracture, (femur).	Sigmoid loop colostomy. Extracutaneous wound debrided.	Evacuated 2-22-1945.
55	Rectum	Injured 2-4-1944.	64	Retrorectal contusion posterior wall rectum appeared sufficiently contained to warrant colostomy.	Rectum mobilized, shell removed, removed. Sigmoid loop colostomy. Distal wound debrided.	Abductus of lower limb, left lung developed; patient very ill, about 4 inches of sigmoid colon herniated through colostomy wound. Evacuated about 10th post-operative day; in good condition.
56	Rectum	Injured 2-1944. Multiple wounds (shell fragments).	12	Rectosigmoid perforated; anterior wall severely lacerated in transverse colon, but no perforation. Pelvicum perforated; coccyx terminalis divided. One intraperitoneal, was extraperitoneal perforation, moderate size, in bladder. Femur perforating wound, left frontal region, compound comminuted fracture of skull.	Perforations in intestines and bladder sutured. End to end anastomosis at point of divided ileum. Transverse loop colostomy. Coccyx inserted in bladder allowed to herniate through lower part of abdominal incision. (Wound debrided; coccyx; distal defect repaired with peritoneal patch).	Abductus of left lower limb perforated because dyspnea, cyanosis. Died on 6th post-operative day. Autopsy: $\frac{1}{2}$ b / d m thought to be main cause of death. Also found perforations, anteriorly left lower limb of lung, multiple small abscesses of that lobe.
57	Rectum	Injured 2-20-1945. Admitted in severe shock, pale, without perceptible blood pressure. (Blood tests) b d m. Wound in left buttock. During 24 hours previous operation patient received 2,000 cc. whole blood. Later blood pressure 170/80. Thought to be hemorrhage. Perforations were present.	64			Patient died during operation. Colostomy performed quickly to stop hemorrhage, if present, and to permit drainage of blood. It was of no avail. About 1200 cc. of blood coming from perforated cavity; generalized peritonitis. Large hole, anterior aspect of rectum, and incision posterior to it on posterior resection. Free perforations in ileum. Large retroperitoneal pelvic abscesses.
58	Rectum	Injured 2-27-1944.	12	Tear 3 cm. long in rectum. Great local contamination; early perforation. Small bowel perforated 3 times; bladder twice.	Distal wound debrided. Colostomy. Rectal, bladder perforations sutured. Sigmoid loop colostomy. Periprosthetic colostomy. Two sets of distal ileum resected.	Patient died 48 hours after operation. Death followed due to traumatic, operative shock, aggravated by great local contamination.

RÉSUMÉ 70 CASES OF INJURY TO THE LARGE INTESTINE AUTHORS' SERIES—Continued

Case	Part Injured	Clinical history	Hours between injury and operation	Pathologic findings	Operative procedure	Comment
69	Rectum	Injured 0-5 1944.	2	One perforation on each lateral wall of rectum, both retroperitoneal, cm diameter. Marked retroperitoneal hemorrhage about rectum, sigmoid bladder. Gas, massive amounts, extended to perit. cavity from rectum up along descending colon, 1 to sigmoid. Mesentery. Compound fracture, left humerus, left femur.	Celiotomy. Transverse loop colostomy. Buttock wound debrided. Drain placed down to rectum. Nothing done to remaining wounds because surgeon felt patient would not tolerate further surgery. Condition remained poor and on the second postoperative day gas gangrene detected. Left arm amputated lower extremity wounds debrided. Patient condition was poor during procedure; remained in shock died shortly afterward.	Autopsy: subcutaneous emphysema, whole left hemithorax. Intermuscle hematoma from shoulder showed no evidence of clostridial myositis. Pathologist: "Severe left pulmonary embolism so severe that it was probably the immediate cause of death. Moderate nonfatal fat embolism. Death due to combination of traumatic and operative shock, gas gangrene pulmonary fat embolism."
70	Rectum	Injured 8-4 1945.	5	Perforating gunshot wound entrance above symphysis pubis. Exit in left buttock. Severe hemorrhage, region of hypogastric vein. Two intraperitoneal perforations (rectum) three distal ileum. Gross fecal material, incompletely digested food (small bowel contents) in peritoneal cavity.	Celiotomy. Bleeding vein ligated. Perforation in intestines closed. Sigmoid loop colostomy. Left buttock wound debrided.	Second day postoperatively 1000 c.c. sanguiferous fluid evacuated from peritoneal cavity. Catheter left in situ; drained approximately 1000 c.c. day. Cystoscopy 7 days after operation. Suprapubic catheter inserted; 3 days after operation fecaluria developed about suprapubic catheter. Next day severe hemorrhage through anal abdominal fistula; patient went into severe shock; was operated on. One perforation in rectum had reopened as reported. Fecal in situ through blow to abdomen. Patient died 16 days after injury. Autopsy 5 cm. perforation in distal ileum just opposite short suture line in gut; from this hole feces were extruding. Fecal matter could be expressed from one of rectal suture lines. Two perforations, each about 3 mm in diameter found in intraperitoneal part of bladder. Generalized fibrinopurulent peritonitis. Death due to peritonitis, which developed result of missing two small triangles in holes in bladder (first operation).

Case 64 cannot be classified exactly. The patient had some blood in the area of the rectosigmoid as seen at proctoscopy before the operation. No perforation was found. At celiotomy there was hemorrhage about the rectosigmoid. In any case such as this one in which damage is suspected even though not proved we think colostomy should be done.

SUMMARY AND CONCLUSIONS

Seventy cases of injury to the colon and rectum in which the patients were treated in an evacuation hospital with a mortality rate of 27 per cent are presented. The literature is reviewed. Im-

portant factors in the treatment and prognosis are analyzed. The presence of shock before or during the operation, the presence of gross fecal contamination of the peritoneal cavity and multiplicity of wounds, were found to be of especial importance.

A review of the results of the three principal operative methods of early treatment of wounds of the colon showed that the mortality rate in World War II when exteriorization without resection was employed was 39 per cent when suture plus proximal colostomy was employed the rate was 37 per cent when suture alone was used the rate was 22 per cent. Usually the procedure of choice in wounds of the colon is exten-

RÉSUMÉ: 70 CASES OF INJURY TO THE LARGE INTESTINE; AUTHORS' SERIES—Continued

Case	Part Injured	Clinical History	Time between injury and operation	Pathologic Findings	Operative procedure	Comment
60	Rectum	Injured 2-3-1945. Opened. 2-7-1945. 545 m		Fracture, corryal perforation on 10 diameter extraperitoneal rectum.	Sigmoid loop colectomy. Peritach wound debrided. Cecostomy.	Evacuated: 2-8-1945; doing well.
61	Rectum	Injured 3-10-1945		Perforation, on diameter rectum, just above anus.	Peritach wound debrided. Sigmoid loop colectomy.	Evacuated: 3-17-1945. In good condition.
62	Rectum	Injured 2-3-1945. Fracture, sacrum.	23	Perforation, anterior postero-lateral, extraperitoneal part of rectum.	Colectomy. Sigmoid loop colectomy. Sacral wound debrided, retrorectal incision.	Suprapubic cystostomy required because patient unable to void. Evacuated 2-3-1945 in good condition.
63	Rectum	Injured 4-1-44. Perforating gunshot wound entered left buttock, exited left groin.	4	Compacted colon united fracture, pubis, sacrum. Lateral incision, body found much of rectal wall, but perforation rate found at rectum not proved.	Sigmoidectomy. Sigmoid loop colectomy.	Evacuated: 4-13-1945. On 3-13-1945, peritach wound was closed, healed, colon at anus still in use.
64	Rectum	Injured: 3-7-1945		Sigmoidectomy showed wound on anterior of fresh blood coming from rectum, wound colon, but no hole seen in wall of colon. Anteroperitoneal hemorrhage along anterior wall of rectum and retroperitoneal colon. Colon wound comminuted fracture, (blow).	Sigmoid loop colectomy. Excise wound debrided.	Evacuated: 3-23-1945.
65	Rectum	Injured 2-4-44	24	Retrorectal contusion, posterior wall rupture appeared sufficiently contained to warrant colectomy.	Rectum mobilized; shell fracture exposed. Sigmoid loop colectomy. Peritach wound debrided.	Amputation of lower limb, left leg developed patient very ill, about 2 weeks of sigmoid colon herniated through colectomy wound. Evacuated about 25th post-operative day in good condition.
66	Rectum	Injured 2-3-1944. Multiple wounds (shell fragments).		Retroperitoneal perforated, no pool and muscle laceration in transverse colon, but no perforation. Jejunum perforated (antitransectal) divided. One intraperitoneal, one extraperitoneal perforation, moderate size, in bladder. Severe penetrating wound, left frontal region, compound comminuted fracture of skull.	Perforations in intestines and bladder: returned. Lacerated antitransectal wound of divided duodenum. Transverse loop colectomy. Catheter inserted in bladder allowed to pass through lower part of abdominal incision. Wound wound debrided in cavity; dorsal defect repaired with pedunculated patch.	Amputation of left lower limb patient because dysenteric, cyanotic. Died on 6th post-operative day. Autopsy: very bad damage thought to be main cause of death. Also hemorrhage, pneumonia, abscesses left lower lobe of lung, multiple small abscesses of left lobe.
67	Rectum	Injured 2-20-1945. Admitted in severe shock, poisoning, without perceptible blood pressure. Rigid, cold. Wound in left buttock. During 20 hours preceding operation patient received 2000 cc. whole blood. Later blood pressure 72/60. (Thought to be hemorrhage, peritonitis very present).	24			Patient died during induction. Colectomy performed quickly because hemorrhage, if present, and to prevent escape of feces. It was of fecal material blood in peritoneal cavity generalized peritonitis. Large hole, extensive aspect of rupture, and laceration produced by the peritoneal reduction. Five perforations in ileum. Large retroperitoneal pelvic hematoma.
68	Rectum	Injured: 2-17-1944		Tear 3 cm. long in rectum direct focal contusion caused by perforation. Small bowel perforated 2 times, bladder torn.	Sacral wound debrided. Colectomy. Rectal, bladder, small bowel, and sigmoid loop colectomy. Suprapubic cystostomy. Two feet of distal ileum resected.	Patient died 24 hours after operation. Death believed due to traumatic, operative shock, exacerbated by gross focal contamination.

RÉSUMÉ 70 CASES OF INJURY TO THE LARGE INTESTINE AUTHORS SERIES—Continued

Case	Part injured	Clinical history	Hours between injury and operation	Pathologic findings	Operative procedure	Comment
69	Rectum	Injured 10-3-1944	2	One perforation on each lateral wall of rectum, both retroperitoneal, 1 cm diameter. Marked retroperitoneal hemorrhage about rectum sigmoid bladder. Gas, in massive amounts, extended retroperitoneally from rectum up along descending colon, into sigmoid mesentery. Compound fractures, left humerus, left femur.	Celiotomy. Transverse loop colostomy. Buttock wound debrided distal inserted down to rectum. Nothing done to remaining wounds because surgeon felt patient would not tolerate further surgery. Condition remained poor and on the second postoperative day gas gangrene detected in left arm. Second operation left arm amputated, lower extremity wounds debrided. Patient died while in poor condition during procedure; removed distal shock; died shortly afterward.	A toxy subcutaneous crepitation, whole left hemithorax, but muscle section taken from shoulder showed no evidence of bacterial myositis. Pathologist: "Severe fat pulmonary embolism, so severe that it was probably the immediate cause of death. Moderate number renal fat emboli. Death due to combination traumatic and operative shock, gas gangrene, pulmonary fat embolism."
70	Rectum	Injured 5-4-1945	5	Penetrating gunshot wound entrance above symphysis pubis; exit left buttock. Severe hemorrhage region of hypogastric vein. Two intraperitoneal perforations in rectum, three in distal ileum. Gross fecal material, (incompletely digested food (small bowel contents) in peritoneal cavity.	Celiotomy. Bleeding vessel ligated. Perforation in intestines closed. Sigmoid loop colostomy. Left buttock wound debrided.	Second day postoperatively 2000 cc. sputum from sputum evacuated from peritoneal cavity. Catheter left in situ; drained approximately 1500 cc. a day. Cystoscopy 7 days after operation. Suprapubic catheter inserted 5 days after operation. Fecal fistula developed about suprapubic catheter. Next day severe hemorrhage through supra-abdominal incision; patient went into severe shock; was operated on. One perforation in rectum had reopened was resected. Fecal matter in cecum and distal rectum through abdominal wound. Patient died 16 days after injury. Autopsy: 1 cm. perforation in distal ileum just opposite short suture line 1 gut. from this hole feces were extruding. Fecal matter could be expressed from one of rectal suture lines. Two perforations, each about 5 mm. in diameter, found in intraperitoneal part of bladder. Generalized fibrinopurulent peritonitis. Death due to peritonitis, which developed as result of missing two small intraperitoneal holes in bladder first operation.

Case 64 cannot be classified exactly. The patient had some blood in the area of the rectosigmoid as seen at proctoscopy before the operation. No perforation was found. At celiotomy there was hemorrhage about the rectosigmoid. In any case such as this one in which damage is suspected even though not proved we think colostomy should be done.

SUMMARY AND CONCLUSIONS

Seventy cases of injury to the colon and rectum in which the patients were treated in an evacuation hospital with a mortality rate of 27 per cent are presented. The literature is reviewed. Im-

portant factors in the treatment and prognosis are analyzed. The presence of shock before or during the operation, the presence of gross fecal contamination of the peritoneal cavity and multiplicity of wounds were found to be of especial importance.

A review of the results of the three principal operative methods of early treatment of wounds of the colon showed that the mortality rate in World War II when exteriorization without resection was employed was 39 per cent when suture plus proximal colostomy was employed the rate was 37 per cent when suture alone was used the rate was 22 per cent. Usually the procedure of choice in wounds of the colon is exteri-

onization. Suture with performance of proximal colostomy is a sound procedure in some cases. Suture alone has a more limited use. The method chosen should depend on the location and size of the intestinal wound and the condition of the patient. Large, ragged wounds should be exteriorized. Suture alone and suture with proximal colostomy should be used for smaller wounds and for wounds in which more extensive procedures are contraindicated by the general condition of the patient.

Intraperitoneal wounds of the rectum must be sutured and proximal colostomy performed.

Extraperitoneal wounds of the rectum are in a separate category. Wide drainage to the exterior should be established and proximal colostomy should be carried out. When injuries have been treated thus, the mortality rate associated with the injuries has decreased to around 6 per cent, by far the lowest mortality rate associated with wounds in any part of the large intestine.

An analysis of the 70 cases has been arranged according to the anatomic situation of the injury in the colon and rectum. In addition a résumé of the 70 cases is included.

ABSTRACTS OF CURRENT LITERATURE

SURGERY OF THE HEAD AND NECK

EYE

Paralysis of Vertically Acting Muscles. FRANCIS
HEED ADLER. *Am J Ophth.*, 1948 31 387

In the present article the author discusses some confusing factors in the diagnosis of paralysis of the vertically acting muscles.

Differential diagnosis is difficult because two muscles appear to be paralyzed in cases of paralysis of the vertically acting muscles.

It is pointed out that there are two groups of cases.

Included in the first group are cases in which no single lesion could possibly involve both muscles—the superior rectus of one eye together with the superior oblique of the opposite eye or the inferior rectus of one eye together with the inferior oblique of the opposite eye. In these cases only one muscle is actually paralyzed and the seemingly paralyzed muscle in the opposite eye is underacting on the basis of Hering's law. When the paralyzed eye is habitually used to fix, the effect of a paralysis of one muscle extends to the activities of other muscles in the same eye and in the opposite eye.

The second group consists of cases in which a single lesion affects the elevator or the depressor muscles of one eye or both superior oblique muscles. On anatomic grounds the elevators and depressors of one eye can be caught in the orbit by scars and growing tumors, or the nuclei of origin of their nerves may be damaged by small lesions in the pons. Both fourth cranial nerves may be caught as they cross each other before emerging on the posterior face of the brain stem.

Pathology of Mucous and Salivary Gland Tumors in the Lacrimal Gland and the Relation to Extraorbital Mucous and Salivary Gland Tumors. ERIK GODTFREDSEN. *Brit J Ophth.* 1948, 31 171

The author discusses the pathology of mucous and salivary gland tumors in the lacrimal gland and their relations to extraorbital mucous and salivary gland tumors. The investigation is based on cases of mixed tumors in the lacrimal gland observed in the Eye Department of Karolinska Sjukhuset Stockholm within the 15 year period from 1932 to 1946. Of 78 cases of orbital tumors 52 were verified as proper tumors 5 were pseudotumors and 21 were not verified. Of 52 orbital tumors 36 were primarily orbital (18 originating in the lacrimal gland, 10 mixed and 8 lymphomatous) 8 were neural from the optic nerve 6 were skeletal 3 vascular and 1 was a dermoid cyst.

Tumors of the lacrimal gland constitute about one-fourth of the comparatively rare orbital tumors.

Histopathologically there are two main types the fibromyxoeplithelioma and the basalloma, both of which may be either benign or malignant. Transitional forms and even different phases may occur within one tumor so that differential diagnosis may be difficult or impossible.

The clinical findings included exophthalmos in 6 cases visual impairment in 2 cases ptosis in 1 case and metastasis to the cervical glands in another.

Although lacrimal gland tumors are superficial and accessible for surgical and radiological treatment the results of treatment are poor. Despite excision with or without irradiation only 5 of the present 10 patients are alive one with recent recurrence the others after fairly short periods of observation. Two of these 5 tumors were histopathologically diagnosed as malignant.

Mixed tumors of the lacrimal gland, previously regarded as histologically and biologically polymorphous tumor forms are now considered morphologically simple and lacrimal gland tumors resemble mucous and salivary gland tumors in other regions. After the clinical diagnosis of lacrimal gland tumor the nature of the tumor should be ascertained by biopsy specimen. Basalioma (which resembles basal cell cancer of the skin) is practically always malignant. Fibromyxoeplithelioma is usually benign.

Benign tumors should be excised by Koenlein's operation or by anterior orbitotomy. Malignant tumors should be given preoperative x ray treatment (4,000 to 5,000 roentgens) followed by evisceration of the orbit a month later. Even if the tumor responds favorably to irradiation evisceration should not be omitted.

The more exact the diagnosis the better are the chances of response to treatment, especially if treatment is instituted early.

Godtfredsen emphasizes the histopathologic and biologic parallelism between tumors of the extraorbital mucous and salivary glands and tumors of the lacrimal gland of the mixed type.

JOSHUA ZUCKERMAN M.D.

The Problem of Sympathetic Ophthalmia. BERNARD
SAMUELS. *Am J Ophth.* 1948 31 397

The author discusses the problem of sympathetic ophthalmia. He points out that in this condition a specific infiltration occurs in the pigmented highly vascular uvea. This consists of three elements lymphocytes, epithelioid cells, and giant cells.

Wounds in the danger zone i.e., over the ciliary body are more serious than wounds elsewhere because prolapse of uveal tissue can occur more readily in this area. The larger the perforation the greater the hazard of prolapse with incarceration.

Sympathetic ophthalmia may also follow operations for glaucoma, but not operations for detachment of the retina. Generally speaking, as long as an eye remains hard after an operation the probability of sympathetic ophthalmia is remote. Cataract extraction and operations for glaucoma are the most common surgical procedures which may result in sympathetic ophthalmia. The following operations are also considered hazardous: iridodonesis, eversion and repair of iridodialysis.

Indectomy for relief of secondary glaucoma should always be avoided. Paracentesis is the only safe procedure. A complicated cataract which develops in a sympathizing eye should not be removed for many months.

From 2 to 13 per cent of all cases of sympathetic ophthalmia originate in eyeballs with post-traumatic septic endophthalmitis.

After septic panophthalmitis, the incidence is about 3 per cent.

Retention of an intraocular foreign body results in irritability which may excite irritation of the other eye.

Clinically sympathetic irritation precedes sympathetic inflammation. Irritation is a warning of impending sympathetic ophthalmia. It disappears within a few days after enucleation of the injured eye. Acute inflammation that is sympathetic ophthalmia is manifested in the uninjured eye by a disturbance of vision, pain, fine greyish keratic precipitates, synechias, vitreous opacities, and small yellowish patches in the choroid.

In sympathetic iritis the entire posterior surface of the iris may be agglutinated to the capsule of the lens. In iritis serosa, the pupil is free. In plastic iritis the adhesions are incomplete and confined to the pupillary zone. The presence in the anterior chamber of greyish nodules at the pupillary border extending to the lens capsule, is considered the most significant clinical sign of sympathetic ophthalmia.

It is important to know when to enucleate an injured eye and when not to enucleate it. The injured eye should be enucleated (1) when the fellow eye is irritable even if it be apparently normal, (2) when keratic precipitates appear in the fellow eye, (3) when there is a hope of usefulness of the eye and (4) when endophthalmitis is present.

The injured eye should not be enucleated (1) when a wound heals properly, the tension is favorable, sight is retained, and the fellow eye shows no irritation, (2) when the injured eye still has some vision after the fellow eye has become inflamed, (3) when both eyes are violently inflamed, and (4) when panophthalmitis is present. In this case, excision should be postponed until the inflammation has sub-

EAR

The Repair of the Ear Drum in Blast Injuries.
SUMNER HAROLD BARON. *Ann. Otol. Rhinol.* 9:48 57-743.

The author's experience with blast injuries to the ear were with few exceptions in accord with that reported by others.

Tinnitus and temporary deafness were constant early symptoms. Transient vertigo was often present. Deafness was of the conduction type superimposed upon a temporary perception deafness. Hearing was usually impaired more in those cases in which there was an unruptured drum. In this series of cases the incidence of complicating otitis media was high. It was noted that perforations with infection healed as rapidly as those without infection. The drum membrane healed in some cases even when three-fourths of its total area was destroyed, provided that no part of the perforation reached the sulcus tympanicus. The use of prostheses placed over the perforation increased the incidence of complete healing.

JOHN R. LINDSAY, M.D.

Facial Paralysis in Otology. J. BROWN FARRIOR. *South. M. J.* 9:48, 4 348.

Facial paralysis, the most grotesque complication in otology presents a grave problem, which is a stimulus to every otologic surgeon. The timely and accurate management of facial paralysis will result in maximal recovery and minimal residual deformity whereas delay or inept management will leave a lifelong stigma upon the patient as well as upon the surgeon.

The classic work of Ballance and Ducl is the foundation of our modern concepts of the otologic management of facial paralysis. The uniformly remarkable success of their experiments on facial nerve grafting provided world-wide stimulus in this field of surgery.

The author gives the following summary:

Intratemporal operations on the facial nerve include simple decompression, decompression and end-to-end anastomosis, decompression rerouting and end-to-end anastomosis, or decompression and nerve grafting.

Facial paralysis resulting from basilar skull fractures may be amenable to otologic surgical treatment if the lesion involves the middle ear. Exploration should be considered when there is loss of response to faradic stimulation.

Facial paralysis developing early in the course of acute otitis media and mastoiditis will usually respond to management of the primary pathologic process.

Facial paralysis occurring during the destructive stage of acute mastoiditis or in chronic mastoiditis demands immediate surgical intervention.

Delayed facial paralysis developing in the post-operative period of any otologic operation should be treated conservatively unless there is loss of response to faradic stimulation.

is pointed out that miotics may increase the tendency to the formation of central synechia and iriditis may produce glaucoma. Administration of salicylates, mercury, salvarsan, tuberculin, preparations, penicillin, and fever therapy may aid.

JOSEPH A. ZUCKERMAN, M.D.

Immediate facial paralysis developing during any otologic operation demands immediate exploration and should ever be treated by hopeful expectancy.

Restoration of the continuity of the facial nerve itself is indicated if the cut ends of the nerve are accessible and the muscles of the face are contractile. Accessible lesions are situated between the geniculate ganglion and the pes anserinus. With restoration of continuity of the facial nerve itself a good result is to be expected. This is the only method which will restore bilaterally co-ordinated emotional facial expression.

The importance of facial paralysis has been greatly overstressed as a possible sequel of the fenestration operation.

Decompression of the facial nerve may be indicated in those cases of Bell's palsy which show loss of response to faradic stimulation for 6 weeks.

The article is illustrated with a very good anatomic drawing.

JOHN F. DUBIN, M.D.

NOSE AND SINUSES

Plastic Dacryocystorhinostomy (Dacriocystorhinostomia plastica). FERNANDO LINHARES. *Rev. brasil cir.* 1948 17 37

The author reviews the anatomy, histology, and physiology of the lacrimal apparatus and lists rhinogenic causes predisposing to dacryocystitis, such as deviation of the septum, atrophic rhinitis, and nasal polyps. The author presents statistics of 50 cases in which operation was done according to Dutempé's technique slightly modified by the author with a high percentage of cures.

Injections of vitamin K and calcium are given during the preoperative period. The operation is performed under regional and local anesthesia. The main step of the operation consists of passing a silk thread without cord through the lower lacrimal canal.

JOSEPH H. NARAT, M.D.

The Operative Treatment of Ozena. A RÉTHI, J. *Lar. Otol. Lond.* 1948 62 139

The essential feature of ozena is the atrophy of the mucosa, the glands of which undergo destruction. Thus the secretion decreases and becomes thick. On the other hand, the nasal cavity becomes wider and larger, which allows too much air to stream through. Under normal conditions the air becomes warm, clear, and moist while passing through the nose. In ozena the atrophic mucosa is incapable of cleansing and heating the air; simultaneously the air absorbs moisture, being unsaturated from the surface of the pharyngeal and laryngeal mucosa. Thus ozena is characterized by a nasal secretion that contains less moisture and becomes sticky, whereas the air in the enlarged cavity is of greater quantity than under normal conditions and poor in vapor. In this way the secretion soon becomes dry. This dry substance is responsible for the factor leading finally to a social inferiority complex in the patients. Further complaints are the frequent headache, anosmia, and

Fig. 1 (Linhares) Passing a silk thread through the lower lacrimal canal.

paresthesia due to engorgement of the nasal meatus by the dry masses in spite of the wide nasal cavity. After some time the pharynx and larynx become dry and catarrhal depletion of the decomposed secretion gives rise to alterations of the alimentary tract, bad nutrition, and anaemia.

Despite the many symptoms, we are completely ignorant as to the real cause of the condition. The theories are interesting but in no way have led to proper treatment.

The operative procedure is described in detail and 5 illustrative figures are presented. It consists essentially in making a mucosal flap of the septum containing both cartilaginous and bony portions. It is freed with considerable technical difficulty and left *in situ* for 8 days. The object of the second phase of the operation is to push the flap toward the patent side of the nose where it will form a transverse vertical wall occluding about 90 per cent of both meati.

The third phase is carried out between the tenth and fourteenth days and consists of transplanting Stensen's duct to either of the maxillary sinuses, but never both.

JOHN F. DUBIN, M.D.

MOUTH

Reevaluation of the Implantation of Fascial Strips through the Masseter Muscle for Surgical Correction of Facial Paralysis. (Report of 3 Additional Cases). NAL OWEN. *Ann. Otol. Rhinol.* 1948 57 55

In November 1946 the author presented the technique and results of fascial and muscle transplants for the correction of facial paralysis. In this article he gives the results in the patients and describes the operations on 3 new patients and reoperation in 2 of the cases in the previous series.

The author believes that the direct attachment of the muscle fasciculi to the paralyzed muscles offers a less satisfactory result than the use of fascial strips which connect the masseter muscle to the paralyzed

Sympathetic ophthalmia may also follow operations for glaucoma but not operations for detachment of the retina. Generally speaking, as long as an eye remains hard after an operation the probability of sympathetic ophthalmia is remote. Cataract extraction and operations for glaucoma are the most common surgical procedures which may result in sympathetic ophthalmia. The following operations are also considered hazardous: iridodectomy, enucleation and repair of iridodialysis.

Iridectomy for relief of secondary glaucoma should always be avoided. Paracentesis is the only safe procedure. A complicated cataract which develops in a sympathizing eye should not be removed for many many months.

From 1 to 15 per cent of all cases of sympathetic ophthalmia originate in eyeballs with post traumatic septic endophthalmitis.

After septic panophthalmitis, the incidence is about 3 per cent.

Retention of an intraocular foreign body results in irritability which may excite irritation of the other eye.

Clinically sympathetic irritation precedes sympathetic inflammation. Irritation is a warning of impending sympathetic ophthalmia. It disappears within a few days after enucleation of the injured eye. Acute inflammation that is sympathetic ophthalmia, is manifested in the uninjured eye by a disturbance of vision, pain, fine greyish keratic precipitates, synechias, vitreous opacities, and small yellowish patches in the choroid.

In sympathetic iritis the entire posterior surface of the iris may be agglutinated to the capsule of the lens. In iritis serosa, the pupil is free. In plastic iritis the adhesions are incomplete and confined to the pupillary zone. The presence in the anterior chamber of greyish nodules at the pupillary border extending to the lens capsule is considered the most significant clinical sign of sympathetic ophthalmia.

It is important to know when to enucleate an injured eye and when not to enucleate it. The injured eye should be enucleated (1) when the fellow eye is irritable even if it be apparently normal (2) when keratic precipitates appear in the fellow eye (3) when there is no hope of usefulness of the eye and (4) when endophthalmitis is present.

The injured eye should not be enucleated (1) when a wound heals properly, the tension is favorable, sight is retained, and the fellow eye shows no irritation, (2) when the injured eye still has some vision after the fellow eye has become inflamed, (3) when both eyes are violently inflamed, and (4) when panophthalmitis is present. In this case excision should be postponed until the inflammation has subsided.

It is pointed out that miosis may increase the tendency to the formation of central synechia, and that mydriatics may produce glaucoma. Administration of salicylates, mercury, salvarsan, tuberculin, life preparations, penicillin, and fever therapy may be tried.

JOSEPH ZUCKERMAN M.D.

RAR

The Repair of the Ear Drum in Blast Injuries.
SHELLEY HAROLD BARON, *Ann. Otol. Rhinol.* 1943
571-543.

The author's experience with blast injuries to the ear were with few exceptions in accord with that reported by others.

Tinnitus and temporary deafness were constant early symptoms. Transient vertigo was often present. Deafness was of the conduction type superimposed upon a temporary perception deafness. Hearing was usually impaired more in those cases in which there was an unruptured drum. In this series of cases the incidence of complicating otitis media was high. It was noted that perforations with infection healed as rapidly as those without infection. The drum membrane healed in some cases even when three fourths of its total area was destroyed, provided that no part of the perforation reached the sulcus tympanicus. The use of prostheses placed over the perforation increased the incidence of complete healing.

JOHN R. LUDLOW M.D.

Facial Paralysis in Otology J. BROWN FARRAR.
South. M. J. 1943, 41, 343.

Facial paralysis the most grotesque complication in otology presents a grave problem, which is a stimulus to every otologic surgeon. The timely and accurate management of facial paralysis will result in maximal recovery and minimal residual deformity whereas delay or inept management will leave a lifelong stigma upon the patient as well as upon the surgeon.

The classic work of Ballance and Ducl is the foundation for our modern concepts of the otologic management of facial paralysis. The uniformly remarkable success of their experiments on facial nerve grafting provided world wide stimulus in this field of surgery.

The author gives the following summary:

Intratemporal operations on the facial nerve include simple decompression, decompression and end-to-end anastomosis, decompression, resecting and end-to-end anastomosis, or decompression and nerve grafting.

Facial paralysis resulting from basilar skull fractures may be amenable to otologic surgical treatment if the lesion involves the middle ear. Exploration should be considered when there is loss of response to faradic stimulation.

Facial paralysis developing early in the course of acute otitis media and mastoiditis will usually respond to management of the primary pathologic process.

Facial paralysis occurring during the destructive stage of acute mastoiditis or in chronic mastoiditis demands immediate surgical intervention.

Delayed facial paralysis developing in the post-operative period of any otologic operation should be treated conservatively unless there is loss of response to faradic stimulation.

Immediate facial paralysis developing during any otologic operation demands immediate exploration and should never be treated by hopeful expectancy.

Restoration of the continuity of the facial nerve itself is indicated if the cut ends of the nerve are accessible and the muscles of the face are contractile. Accessible lesions are situated between the geniculate ganglion and the pes anserinus. With restoration of continuity of the facial nerve itself a good result is to be expected. This is the only method which will restore bilaterally co-ordinated emotional facial expression.

The importance of facial paralysis has been greatly overstressed as a possible sequel of the fenestration operation.

Decompression of the facial nerve may be indicated in those cases of Bell's palsy which show loss of response to faradic stimulation for 6 weeks.

The article is illustrated with 4 very good anatomic drawings.

Fig. 1 (Linhares) Passing a silk thread through the lower lacrimal canal.

NOSE AND SINUSES

Plastic Dacryocystorrhinostomy (Dacriodacryorhinostomia plastica) FERNANDO LINHARES. *Rev. bras. cir.*, 1948, 17, 37.

The author reviews the anatomy, histology, and physiology of the lacrimal apparatus and lists rhinogenic causes predisposing to dacryocystitis, such as deviation of the septum, atrophic rhinitis, and nasal polyps. The author presents statistics of 50 cases in which operation was done according to Dutemps' technique, slightly modified by the author, with a high percentage of cures.

Injections of vitamin K and calcium are given during the preoperative period. The operation is performed under regional and local anesthesia. The main step of the operation consists of passing a silk thread without end through the lower lacrimal canal.

JOSEPH K. NARAY, M.D.

The Operative Treatment of Ozena. A. RÉTUI, *J. Lar. Otol.*, Lond., 1948, 62, 139.

The essential feature of ozena is the atrophy of the mucosa, the glands of which undergo destruction. Thus the secretion decreases and becomes thick. On the other hand, the nasal cavity becomes wider and larger, which allows too much air to stream through. Under normal conditions the air becomes warm, clear, and moist while passing through the nose. In ozena the atrophic mucosa is incapable of cleansing and heating the air; simultaneously the air absorbs moisture being unsaturated from the surface of the pharyngeal and laryngeal mucosa. Thus ozena is characterized by a nasal secretion that contains less moisture and becomes sticky, whereas the air in the enlarged cavity is of greater quantity than under normal conditions and poor in vapor. In this way the secretion soon becomes dry. This dry substance is responsible for the factor leading finally to a social inferiority complex in the patients. Further complaints are the frequent headache, anosmia, and

paresthesia due to engorgement of the nasal meatus by the dry masses in spite of the wide nasal cavity. After some time the pharynx and larynx become dry and catarrhal degeneration of the decomposed secretion gives rise to alterations of the alimentary tract, bad nutrition, and anemia.

Despite the many symptoms, we are completely ignorant as to the real cause of the condition. The theories are interesting but in no way have led to proper treatment.

The operative procedure is described in detail and 5 illustrative figures are presented. It consists essentially in making a mucosal flap of the septum containing both cartilaginous and bony portions. It is freed with considerable technical difficulty and left *in situ* for 8 days. The object of the second phase of the operation is to push the flap toward the patent side of the nose where it will form a transverse vertical wall occluding about 90 per cent of both meati.

The third phase is carried out between the tenth and fourteenth days and consists of transplanting Stensen's duct to either of the maxillary sinuses, but never both.

JOHN F. DELPE, M.D.

MOUTH

Reevaluation of the Implantation of Fascial Strips through the Masseter Muscle for Surgical Correction of Facial Paralysis. (Report of 3 Additional Cases) NEAL OWEN. *Ann. Otol. Rhinol.*, 1948, 57, 55.

In November 1946, the author presented the technique and results of fascial and muscle transplants for the correction of facial paralysis. In this article he gives the results in the patients and describes the operations on 3 new patients and reoperation in 2 of the cases in the previous series.

The author believes that the direct attachment of the muscle fasciculi to the paralyzed muscles offers a less satisfactory result than the use of fascial strips which connect the masseter muscle to the paralyzed

one. In this procedure there is less risk of possible injury to the nerve to the masseter muscle, and less danger of loss of muscle tissue due to the secondary infection.

The utilization of fascial strips attached directly to an intact muscle which has normal innervation and carried to the paralyzed muscles furnishes a supportive sling that gives an additional quality of movement upon contraction of the normal muscle. Because of the position innervation, and attachment of the masseter muscle, it is particularly well suited for this purpose.

The author briefly gives some details on the technique of the operation with special strips obtained from the fascia lata.

The fascia should be fixed to the masseter muscle so that it is attached to a point superior to the normal angle of the mouth to assure an upward pull. It is very important not to enter the oral cavity as contamination may result in secondary infection and ruin the end-result.

After the skin incisions have been closed with subcutaneous sutures of nylon and the skin with dermalon ooooo, strips of 1 inch gauze are fixed by colodion to the skin to support the face in position.

Postoperatively these supportive strips are respliced as frequently as necessary and the patient is put on a liquid and semisolid diet for the first month. Thereafter he is permitted to contract the muscles, and later he is instructed to practice facial movements.

The author believes that this procedure is indicated when from 1 to 3 years have elapsed since transection of the nerve when direct nerve anastomosis is not feasible when substitution of the spinal accessory or the hypoglossal nerve is not possible or is not desired or when a nerve anastomosis has been attempted previously and failed.

In the author's series the facial paralysis was due to surgical transection in excision of a tumor or the excision of a neuroma acoustica residual permanent paralysis following Bell's palsy infantile paralysis, and unknown causes.

If the fascial strips are utilized, there is little cause to destroy the innervation of the normal muscle and unless the result is impaired by secondary infection, it offers more than static support to the involved side of the face.

The author gives brief case reports of 3 new cases and of 3 cases in which operation had been done previously.

WILLIAM A. ARBROOK, M.D.

PHARYNX

Acute Polyradiculoneuritis Arising after Peritonsillar Abscess and Accompanied by Increased Antistreptolysin Titer in the Cerebrospinal Liquor. PER FRANK IVERSEN. *Acta med. scand.*, 94:3, 79, 441.

The etiology of polyradiculoneuritis is under discussion the disease itself seems no longer so strictly distinguishable from other similar affections as when

Gullain and Barre first described their syndrome. The albuminocytological dissociation and the flaccid paresis are assumed to be due to an infection by most investigators, while others point to allergic and toxic reactions toward different substances as a possible cause. The condition has been seen as a consequence of diphtheria, but in most cases it has not been possible to demonstrate any specific microbe. The theory which seems to be most favored at present is that we are dealing with a virus disease.

The following case history is presented.

A man, aged 43 years, with a history of several peritonsillar abscesses, and who had a year previously had a general dermatitis, developed another peritonsillar abscess, and 5 weeks later a flaccid quadriplegia occurred with extinguished tendon and plantar reflexes. He experienced a peripherically increasing loss of sensation. The cerebrospinal fluid showed albuminocytological dissociation. After a fortnight's stay in the hospital increased antistreptolysin titer was noted in the cerebrospinal liquor.

After one month's stay in bed there was considerable improvement in strength and sensation.

When the patient came for control examination 3½ months after the paresis set in, there was good strength in all the groups of muscles, as well as normal sensation and reflexes. The cerebrospinal fluid now gives normal findings as regards cells and protein, and the antistreptolysin titer has gone down to 0.

Acute polyradiculoneuritis often starts with an affection of the upper respiratory tract. In this patient who had previously had several peritonsillar abscesses and was suffering from chronic tonsillitis and laryngitis it was natural to consider his paresis in connection with his infection of the respiratory tract. The microbes most frequently found in peritonsillar abscesses are streptococci. It is a well known fact that the antistreptolysin titer in the blood is increased in most cases of peritonsillar abscess. The author assumed that the disease from which the patient was suffering could be due to a streptococcal infection. The author found an increased antistreptolysin titer in his spinal liquor.

Attention is drawn to the similarity between the acute polyradiculoneuritis in this case and ordinary acute nephritis or rheumatic fever. The latter diseases are as we know generally regarded as allergic reactions to an infection. In the author's case the patient's previous general dermatitis pointed to an allergic disposition.

JOHN F. DIXON, M.D.

NECK

Present Day Trends in Thyroid Research. J.H. MILES. *West. J. Surg.* 94:3, 56, 61.

The tempo of thyroid research has increased strikingly principally because of the many new techniques now available. The use of radioactive isotopes of iodine and the employment of new antithyroid agents are perhaps the most prominent of the new techniques. Thyroid research is becoming more fundamental in character and the author

SURGERY OF THE HEAD AND NECK

believes that the phylogenetic approach would yield important knowledge.

Two hormones are involved in the study of the thyroid: the hormone produced by the thyroid gland (TH) and the pituitary hormone which stimulates the thyroid (TSH). The synthesis of the thyroid hormone has been the subject of an extensive amount of investigative work. Thyroxine was first synthesized in the laboratory and this was logically followed by a study of its synthesis *in vivo*. This involves not only the iodination of tyrosine and the condensation of two such molecules to form thyroxine, but the iodide received by the thyroid gland must be oxidized to iodine to be used in this process, and also a protein thyroglobulin must be manufactured to serve as a matrix within the molecule of which the process takes place. This protein also acts as a vehicle for the storage of the hormone in the follicle. Recent work indicates that there may be a specific iodine trapping mechanism in the thyroid. The thyroid gland is not indispensable for the synthesis of iodoprotein and human myxedema has been relieved with mammalian serum protein treated *in vitro* with iodine and artificial thyroprotein has been made by iodinating casein.

Investigation of the control of the thyroid gland is one of the well marked trends of modern thyroid research. Little is known of the sole activity of the thyroid gland. The secretory threshold of the thyroid gland of the thyroid stimulating hormone may be altered by nervous stimuli coming chiefly over the hypothalamic tract and possibly also over the sympathetic pathways to the pituitary situated alongside the blood vessels. The manner in which the thyrotropic hormone affects the thyroid is being subjected to the most active research at present. In acting upon the thyroid cell this hormone becomes inactivated but it can be reactivated by reducing agents. Iodine inactivates it and thiouracil reactivates it. The thyroid-stimulating hormone may be concerned in the production of exophthalmos.

F. J. LEEMAN, JR., M.D.

Calcified Endothoracic Goiter and Median Sternotomy (Goitre endothoracique calcifié et sternotomie médiane) EMILE DELANNOY *Rev. chir. Par.*, 1947 66 271

The question as to whether a retrosternal goiter should be removed from above or by opening of the thorax is much discussed in the literature. Most authors believe that every endothoracic struma can and should be delivered through the superior aperture of the thorax. If necessary the capsule of the gland is incised and the glandular substance removed piecemeal in order to reduce its volume.

Although the author agrees that in most cases it is possible and safer to develop the goiter by the cervical route he shows that there are rare cases in which this procedure is nearly impossible. These cases include those with unusual hardness or calcification of the gland and extensive adhesions to the pleura or

trachea. Furthermore, the piecemeal removal of the mass is sometimes risky because the control of hemorrhage is difficult and in case of adhesion there is the danger of producing a pneumothorax and mediastinal emphysema.

The author has performed 1200 strumectomies among which there were 15 retrosternal goiters. Fourteen of these were removed from above only. In one case it was necessary to perform a sternotomy. This case, a large calcified retrosternal goiter in a 61-year-old woman is reported in detail. The mass involving both lobes of the thyroid was of the consistency of stone and showed extensive calcification. Its weight was 200 gm. and it was adherent to the pleura and trachea. In this case it was necessary to do a median sternotomy down to the third intercostal space.

The author is in favor of median sternotomy rather than lateral thoracotomy with resection of the clavicle. Sternotomy causes less hemorrhage and shock, and the surgeon keeps clear of the internal mammary vessels and the pleura.

WILHELM M. SOLMITZ, M.D.

The Clinical Significance of a Solitary Nodule in the Thyroid Gland MAYO H. SOLLEY STUART LYND-BAY and MORRIS E. DAILEY *West. J. Surg.* 1948, 56 96.

Ninety-six cases of a solitary nodule in the thyroid gland are reported. Twenty-two of the patients had benign neoplasms and 15 had malignant neoplasms. Malignant tumors are more than twice as frequent in males as in females.

In 38 (39.5%) of the patients the solitary tumor was found to be an involutary nodule. A group of acini in an involuting gland enlarges because of excessive colloid formation and compresses the adjacent thyroid tissue which thus becomes atrophic and forms the capsule of the nodule. The small nodule thus formed may increase in size in a number of ways: the original acini may enlarge by epithelial cellular growth; cyst formation may occur; or growth of the thyroid cells between the large acini may occur. The small nodule thus increases in size to form the clinical thyroid tumor.

In 21 of the cases (21.8% of the total) the solitary thyroid tumors were found to be adenomas. These are true neoplasms and may be classified into four groups: embryonal, fetal, simple and colloid. Eighteen additional cases could not be classified as the histological picture resembled both that of an involuting nodule and that of an adenoma.

Two of the nodules were classified as adenomas with invasion microscopically. They had the characteristic pattern of a benign neoplasm but they were invading the adjacent gland locally. No recurrence has been noted in these 2 cases which have been followed for 5 and 11 years respectively. Two additional cases were classified as malignant adenomas. Microscopically they presented the usual histological characteristics of malignancy but they showed no capsular or vascular invasion. Neither of

the tumors has recurred during a follow-up of 6 and 8 years, respectively.

Eleven cases were classified as carcinomas of the thyroid. These tumors presented all of the histological cellular characteristics of malignancy plus invasion and were classified into three groups: papillary carcinoma, 3 cases; adenocarcinoma, 5 cases; and carcinoma, 3 cases.

In addition 2 of the nodules proved to be simple cysts, one was an intracystic papilloma, and one solitary nodule was due to thyroiditis.

The authors conclude that it is apparent that the incidence of benign tumors (82%) and malignant tumors (16%) among single nodules in the thyroid gland warrants radical resection of these nodules. Unless the diagnosis of carcinoma is clinically certain, resection of the cervical lymph nodes is not indicated. The authors are against simple enucleation of a solitary nodule, but advocate removal of the entire lobe.

F. J. LEEHMAN, JR., M.D.

Malignant Tumors in Aberrant Lateral Thyroid
(Tumors malignant in thyroid laterally aberrant). LUNIS
PACIFIC MED. ARCH. *Dis. chir.* 947 69 4 5.

The author presents a case report of malignant aberrant thyroid tissue. A 27 year old female first noted some swelling in the left side of her neck 2 years before she presented herself to the author. She was seen by a doctor who made a diagnosis of tuberculous adenitis and placed her on calcium therapy with no improvement. The swelling kept on increasing in size and was especially large during menstrual periods. She was first seen August 22, 1945 and at this time she had an ovoid mass about the size of a large egg which lay in the left lateral cervical region beneath the sternocleidomastoid muscle. There was no abnormal pulsation; the mass was freely mobile and moved with deglutition. The thyroid gland was normal. The basal metabolism was plus 8.

The patient was operated upon August 24, 1945. The mass was found in the superior carotid triangle extending beneath the sternomastoid muscle. It was easily enucleated and possessed a very vascular capsule. It was made up of three lobes, soft and rubbery in consistency and of a black slate color. It weighed 18 grams.

In two successive operations, March 21, 1946 and February 18, 1947 respectively, two other similar nodes were removed, one about the size of a nut and the other the size of a pigeon's egg.

Histologic examination revealed a papillary epithelial neoplastic tissue in a cystic glandular matrix of aberrant thyroid tissue.

The patient never had any symptoms or loss of weight. She was last seen in March, 1947 and presented no change. The basal metabolism rate remained the same.

A review of the literature is presented. From 1857 to 1939 48 cases were reported, while from 1939 to 1942 86 cases were reported. The increase is attributed to better diagnosis and exact classification.

The lesion does not present characteristic clinical signs and exact diagnosis is considered difficult. These tumors may occur in any of the triangles of the neck and usually there are multiple nodules. The most frequent form is papillary (66%). There has been one case report of sarcoma (Onufrio 1934). Only malignant forms are considered.

The treatment of choice is surgical removal. X-ray therapy was used a great deal formerly but for one reason or another it is now reserved for only inoperable cases. Extensive dissection and resection of regional lymph nodes are advised. There are usually multiple small cell nests which cannot be seen or palpated and this explains the cause of frequent recurrence as seen in the author's patient.

LOUIS J. FROSTEN, M.D.

Papillary Adenocarcinoma of the Thyroid Gland,
So-Called Lateral Aberrant Thyroid Tumors.
B. MARDEN BLACK. *West. J. Surg.* 948 50 34.

The findings in a review of 112 cases of papillary adenocarcinomas of the thyroid gland encountered at the Mayo Clinic in recent years strengthened the belief, held at the clinic for many years, that the lateral cervical papillary tumors are metastatic lesions from a primary papillary adenocarcinoma of the thyroid gland. Conflicting views concerning these tumors, particularly as to whether they are benign or malignant and as to whether there is always a malignant lesion in the thyroid gland in such cases, have led to evident confusion as to the proper management in such cases. Thus, in almost two-thirds of the cases in the small group in which one of the metastatic lesions had been removed at biopsy elsewhere, removal of the primary lesion had not been advised. The evident lack of understanding, generally of the so-called lateral aberrant thyroid tumors, would be dispelled, it seems, if their metastatic nature were widely recognized.

The malignant nature of the primary lesion in the thyroid gland is well illustrated by the fact that a number of local recurrences follow subtotal lobectomy. It can probably be stated definitely that if the papillary adenocarcinoma is larger than a few millimeters in diameter and if it is recognized during operation, a total rather than a subtotal lobectomy should be carried out. In spite of the fact that subsequent operations to remove involved cervical lymph nodes were infrequently not necessary, the author believes that removal of only the involved lymph nodes, generally as a group, is sufficiently radical treatment of the metastatic lesions. Careful examination at stated intervals after the operation to determine whether unremoved lymph nodes have become palpable is, of course, necessary.

In addition to the fact that a primary papillary adenocarcinoma was found in every case in the series, the fact that the primary lesion was always present in the corresponding lobe of the thyroid gland is of importance from the standpoint of treatment. While no contralateral metastatic lesions were observed, involved lymph nodes were

found in the opposite lateral cervical region in 2 cases in which the primary adenocarcinoma involved one lobe and only the isthmus on the opposite side

Mortality Operative Complications, and Recurrence Frequency in the Surgical Treatment of Thyrotoxicosis. ARNE BERTILSEN, ERIK CHRISTENSEN, EGON BAGVU, and POUL BECKER-CHRISTENSEN. *Acta chir scand.*, 1947, 96 Supp. 133

This article was written primarily to help decide whether the medical or the medicosurgical treatment of thyrotoxicosis has been influenced by the use of thiourea derivatives. The recent results of the surgical treatment of thyrotoxicosis are reviewed. The frequency of recurrences and the frequency of unfortunate direct consequences of operation are investigated. The mortality, the complications occurring during and immediately after the operation, the frequency and course of postoperative paresis of the recurrent nerve and of hypoparathyroidism and also the recurrence frequency along with a short survey of the literature are reviewed.

This material on thyrotoxicosis is from Surgical Clinic C of the Rigshospital and includes 910 operations in the 5 year period from April 1940 to April 1945. It contains 910 cases of thyrotoxicosis. There were 777 females and 133 males the ratio being approximately 6 females to 1 male. There were 35 recurrences in the females and 4 in the males. Of the patients with recurrence only 19 had been operated upon previously at the surgical clinic from which these statistics were taken. There were 835 cases of subtotal thyroidectomy, 23 cases of enucleation of toxic adenoma and 13 cases of enucleation and hemithyroidectomy. It is interesting to note that in all cases the anesthesia was local with novocaine adrenaline injected subfascially and subcutaneously behind the sternocleidomastoid muscle and at the superior lateral poles. Resection has been standard during the past few years also in cases of adenoma.

Among these 910 operations for thyrotoxicosis there were 7 deaths. The mortality rate was 0.77 per cent. In 4 of the 6 fatal primary operations the thyrotoxicosis was not fully regulated the basal metabolic rate having been between +45 and +75. In more than half of the cases in this material the operations were performed in stages. The heart complications recognized prior to the operations did not affect the mortality in this material. There were 40 true thyrotoxic crises of which 4 led to death. The mortality in this group of operations for thyrotoxicosis was 0.2, 0 per cent and the mortality among the operations for recurrence in this group was 2.6 per cent.

From the experience obtained the authors believe that it is advisable to exercise restraint in regard to operation in elderly patients and make efforts to induce remission in more or less iodine resistant patients with methimazole therapy alone, or in combination with iodine preparations. In view of the danger of pneumonia it is recommended that

sulfonamide or better penicillin prophylaxis be used in the more severe cases, especially in thyrotoxic crises.

In this group of cases the patients got up on the seventh day after operation and there were only 3 with true thromboembolic complications, two lung infarctions and an isolated slight case of phlebitis in the left lower extremity. The incidence of thromboembolic complications was 0.33 per cent and there was one death due to coronary thrombosis and one due to preoperative cardiac insufficiency with embolism of the extremity. This made 5 cases and a frequency of 0.55 per cent. Asphyxia during and after operation for thyrotoxicosis may be the result of stenosis or a membranous collapse of the trachea, bilateral paresis of the recurrent nerves or compression of the trachea through hemorrhage. There was one true case of membranous collapse in this series. Asphyxia resulting from bilateral paresis of the recurrent nerves occurred in 3 cases. Tracheotomy was performed only once in this material in a patient with a bilateral lesion of the recurrent nerves. Hematoma with incipient asphyxia necessitating reoperation with renewed hemostasis occurred 6 times. In 6 other cases dilatation of the drainage site and expression of the clots were sufficient.

Wound infection occurred in 8 cases. For the definition of tetany the authors require typical carpal spasm or other clonic spasms and do not include the slight forms with paresthesia in the fingers combined with slight hypocalcemia or the quite latent tetany. Among these cases there were 9 of tetany following the primary operations and one case of tetany following a recurrent operation. A frequency of 1.02 per cent among the primary operations and of 2.6 per cent among the recurrent operations. The frequency of tetany for the whole group was 1.02 per cent. There were 23 patients who had slight postoperative hypocalcemia less than 9 mgm. per cent but had no subjective signs of tetany. All of the 10 clinical cases occurred in women as well as 22 of 23 symptomless cases of hypocalcemia. There was no characteristic age distribution. The anatomic pathogenesis of postoperative tetany must be described as not definitely clarified.

Postoperative paresis of the recurrent nerves occurred in 64 patients with a total of 66 pareses, 18 permanent and 48 transitory. Of the transitory pareses, 19 were on the right side and 27 on the left. No case of permanent paresis ever subsided after a period of 6 months. All the permanent pareses were unilateral. Among 835 cases of subtotal thyroidectomy only 1.3 per cent developed permanent paresis. The highest percentage of permanent paresis (25.4%) occurred following the recurrent operations. Of the total material of 66 cases of pareses 48 or 72 per cent disappeared completely. Among this group there were no cases of permanent bilateral paralysis. During the past 6 months the authors employed laryngoscopy during the operation or immediately prior to closing the wound and if a cord was found to be paralyzed the operative wound was reopened.

and the nerves were freed. In the cases in which the nerves were freed the patients were completely cured. In this method they have found the possibility of reducing still more the frequency of permanent injury to the recurrent nerve. Among 647 patients suffering from thyrotoxicosis, 33 (4.9%) proved to have recurrences, while the patients with exophthalmic goiter numbered 25, or 6.3 per cent. There were 7 (2.8%) with thyrotoxic adenoma. It is interesting to note the interval between the first operation and the onset of recurrent symptoms: 9 patients had a second operation in less than one year, 9 between 1 and 2 years, 8 between 2 and 4 years, 2 between 4 and 8 years, and 4 in more than 8 years. The authors cannot even say in advance which cases are particularly disposed to recur. There is scarcely any doubt that recurrences belong to the special indication sphere of the antithyroid substances or of radio-active iodine. It is suggested that careful attention to the way of life of the patients during the first 3 years after a thyroidectomy may be of importance in preventing a recurrence, and the opinion is expressed that in this period women should avoid pregnancy. Thyrotoxic crisis with a poor general condition and a pulse rate of over 140 occurred in 40 cases, 4 of them terminated fatally in spite of vigorous iodine therapy.

There were 167 patients admitted to this department in the 3 years from April 1945 to April, 1947 and 164 operations were performed; there were 151 cases of diffuse hyperplastic goiter, 6 cases of thyrotoxic adenoma, and 10 cases of recurrence. There were 134 subtotal thyroidectomies, and 3 enucleations of toxic adenoma, and 8 resections of recurrent goiter. The authors still prefer local anesthesia for almost all thyroid operations. There were no postoperative deaths. No cases of thrombosis or embolic complications, of tetany or hypocalcemia and no cases of asphyxia occurred. True postoperative crisis with a pulse rate of over 40 occurred in 6 cases but in all cases a normal condition was restored by the intravenous administration of iodine, and the administration of sedatives. The routine postoperative administration of iodine, an antipyretic, and one liter of saline solution parenterally seems to play an important role in the prevention of this complication, which was previously very much feared. While the drugs of the thiouracil group used preoperatively are of immense value in reducing the postoperative crisis, they are of no use at all in manifest postoperative thyrotoxic crisis, because their action is too slow. Among 164 operations for thyrotoxicosis 5 cases of paresis of the recurrent laryngeal nerve occurred. None

drugs alone is still on trial. Most promising preliminary results have been reported with the use of propylthiouracil. RICHARD J. BENDITT, JR., M.D.

An Evaluation of Routine Exposure of the Recurrent Nerves During Thyroid Operations. RICHARD B. CASTELL. *West. J. Surg.* 1948, 56: 77

In the earlier experience at the Lahey Clinic it was found that unilateral nerve injury occurred in 3 per cent of all thyroid operations, and in recurrent cases this rose to as high as 14 per cent. Following the routine exposure of the recurrent laryngeal nerves the incidence of injury has dropped to 0.7 per cent in 4,793 thyroidectomies. In the operative technique used the prethyroid muscles are divided, the inferior thyroid artery is exposed and usually ligated in continuity, and the recurrent laryngeal nerve is identified. The nerve is most frequently injured either at the inferior pole or at its point of entry into the inferior pharyngeal constrictor fibers. The author does not believe that paralysis follows the gentle handling of the nerve incident to its exposure.

Approximately 3 per cent of injuries of the recurrent nerves result in temporary paralysis only and in such cases some motion will be found within from 4 to 6 weeks. Among 750 cases prepared with thiouracil-like drugs and in which this technique was used injuries were observed in 0.9 per cent. Approximately 3 per cent of the patients will have recurrent symptoms of hyperthyroidism following subtotal thyroidectomy. F. J. LEEMAN, JR., M.D.

Laryngocoele. CHEVALIER L. JACKSON. *Laryngoscope* 94: 57, 1955.

A laryngocoele is an anomalous air sac connected with the larynx which is in reality a hernia of the larynx, is lined with mucosa, and is not a tumor. While rare in occurrence, it is often overlooked. Any thing that increases the intralaryngeal pressure, such as coughing, singing, blowing a horn, may be of etiologic significance. Papillomas, cancer or syphilis may be associated with this condition. Laryngocoeles may be of the internal or external type; the external type is outside of the thyrohyoid membrane and is seen as a bulge in the neck, the internal type is located inside the thyroid cartilage.

Hoarseness is the most important symptom; dyspnea may be present; an external bulge may be seen, or a hissing sound may be audible when pressure is made on the external bulge. Plainographic x-ray studies in the establishment of the diagnosis.

Bilateral Granuloma of the Larynx following Endotracheal Anesthesia J W McLAURIN *Laryngoscope* 1947 57 796.

A case is reported in which a granuloma of the larynx resulted from endotracheal intubation. This is a rare complication being the sixth reported case. Apparently the granulomas originate in a traumatic ulcer of the cord which upon healing slowly from the periphery results eventually in a pedunculated lesion. The lesion should not be removed until it has become pedunculated when its removal is easy and healing rapidly occurs. F J LEBEMANN, JR. M.D.

The Surgical Treatment of Carcinoma of the Hypopharynx and the Esophagus HAROLD WOOLLEY *Brit J Surg.* 1948, 35 249.

Methods for the removal of malignant lesions of the hypopharynx and esophagus are described together with methods of reconstruction of the continuity in this well illustrated article. Most malignancies of the esophagus and pharynx are epidermoid carcinomas. The subject is divided into 3 parts: (1) lesions involving the hypopharynx and the upper end of the esophagus; (2) lesions occurring in the mid-portion of the esophagus; and (3) carcinomas of the lower portion of the esophagus.

Carcinoma of the retrocricoid area of the hypopharynx is almost entirely confined to the female although about 80 per cent of the carcinomas of the esophagus occurs in men. In addition to x-ray studies esophagoscopy should be performed in those who complain of discomfort in swallowing for lesions of the hypopharynx often do not visualize with the barium swallow. Metastases are found most frequently in cases involving the lower third of the esophagus and the more highly differentiated tumors seem to offer the best prognosis.

Operation of the hypopharynx and the upper esophagus should not be undertaken in advanced cases or those in which metastatic nodes are present. Sacrifice of the larynx is necessary in lesions occurring in the pyriform fossa or anterior wall of the pharynx

involving the back of the larynx. After the establishment of an adequate collateral circulation to skin tubes fashioned at the time of the excision of the lesion, the patient may take liquids by mouth. Lesions involving the retrocricoid area do not necessitate laryngectomy although tracheotomy is deemed advisable to combat postoperative laryngeal edema for a few days. Skin tubes are planned at the time of the original surgery in a similar manner to those for lesions in the pyriform fossa.

Because of the high incidence of intra-abdominal metastases occurring in lesions of the intrathoracic esophagus, the author believes that laparotomy is desirable and that a temporary jejunostomy should be performed in the cases selected for resection. Through a left thoracotomy the esophagus is mobilized. After the diaphragm is incised, the stomach is mobilized along both curvatures and freed from the spleen. The right phrenic nerve is crushed to paralyze the diaphragm. Inversion of the lower end of the esophagus into the stomach is performed after division of the esophagus. The stomach is brought into the left thorax and anchored as high as possible to the parietal pleura preceding anastomosis between the esophagus well proximal to the tumor and stomach. The jejunostomy tube is used to feed the patient postoperatively starting after 72 hours. Fluids by mouth are usually tolerated by the end of the second week at which time the jejunostomy tube is removed.

A combined thoracoabdominal incision is made for removal of lesions of the lower end of the esophagus after preliminary exploration of the peritoneal cavity through the abdominal portion of the incision. Anastomosis between the stomach and the esophagus is done within the thoracic cavity. Following the resection and anastomosis a jejunostomy is performed before closure of the wound. Endotracheal anesthesia with positive pressure control of respiration is used and thoracotomy wounds are drained by a closed system. Emphasis is placed on the careful selection of cases in which the diagnosis of carcinoma has been made reasonably early. JOHN L. BELL, M.D.

SURGERY OF THE NERVOUS SYSTEM

BRAIN AND ITS COVERINGS; CRANIAL NERVES

The Connections of the Frontal Lobes of the Brain.
W. E. LE GROS CLARK. *Lancet*, Lond. 1918, 1 353.

In recent years the increasing therapeutic use of prefrontal leucotomy has directed attention far more closely to the functions of the frontal lobes and has provided much material for their elucidation. The functions of the frontal lobes as of all other parts of the brain, must depend ultimately on their anatomical connections and a review of these will therefore be an important preliminary to physiological and psychological studies.

The frontal cortex is commonly regarded as primarily an association area, that is, a cortical area predominantly concerned with the reception of impulses which pour into it from other regions of the cerebral cortex. This conception, according to the author, has no sound anatomical basis, for there is no evidence of the existence of massive long association tracts streaming forward into the frontal lobe from all the other regions of the cerebral cortex. It also obscures the fact that much of the frontal cortex is an efferent projection area comparable with the visual or auditory areas of the cortex.

A large proportion of the frontal cortex is a projection area for the dorsomedial nucleus of the thalamus, the medial nucleus of human anatomical terminology. According to Bletlinger (1947) the dorsomedial nucleus connects with all the areas from 8 to 2 in the frontal lobe of the monkey the fibers going to these areas approximately in order from the caudolateral part of the nucleus to the anteromedial part.

The nature of the impulses conveyed to the frontal areas of the cortex from the dorsomedial nucleus can as yet hardly be defined in detail from the purely functional point of view but it is now possible to state with confidence that the dorsomedial nucleus is essentially a relay station for the transmission of impulses originating in the hypothalamus. More recently this connection has been established by studying the effect of hypothalamic stimulation on action potentials in the cortex. Thus there are clearly functional pathways from the hypothalamus to the cortex via the dorsomedial nucleus, and direct efferent connections from the cortex to the hypothalamus.

It may be inferred from these anatomical data that the impulses which stream into the frontal lobes from the dorsomedial nucleus represent the resultant not only of the activities of the hypothalamus but also of some of the activities of the thalamus proper. The frontal cortex also receives hypothalamic stimuli from another source by way of the anterior nucleus of the thalamus. This nucleus is known, from experimental work on lower animals,

to project on to the limbic areas in the cingulate gyrus (areas 24 and 25). Until more is known of the connections and functions of the hippocampus, the significance of the projection from the anterior nucleus of the thalamus to areas 24 and 25 must remain in doubt.

From what has been said, one fact which stands out very strongly is that, by way of the anterior and dorsomedial nuclei of the thalamus, the greater part of the cortex of the frontal lobe must be regarded as a projection area receiving the products of activity of the hypothalamus, in the same way that the visual cortex is the projection area for retinal activities, or the auditory cortex for cochlear activities. In the case of the anterior limbic areas, the hypothalamic connection serves mainly as a relay station for the hippocampus.

The author next considers the intercortical connections of the frontal lobes, that is the association fiber systems which link its different cortical areas with other cortical areas of the cerebral hemisphere. So far as afferent association-fiber systems are concerned, connections to area 8 from area 6 have been established and probably similar short interconnections exist between other frontal areas. As regards the efferent association tracts, connections have been described in the monkey's brain conducting in a forward direction from area 8 of the occipital cortex to area 8.

One of the long association tracts which exist in the cerebral hemisphere has its origin in area 8 of the frontal lobe, the area which is included in the "frontal eye field." This fasciculus passes backward and extends directly to the parastriate area (area 18) surrounding the visual cortex of the occipital lobe. Another efferent association tract from the frontal lobe takes origin from area 47 (area orbitalis agranularis) and curves downward and backward as the uncinate fasciculus to reach area 38 in the pole of the temporal lobe. Degeneration in the uncinate fasciculus has been reported by Meyer *et al.* (1947) in their series of leucotomized human brains.

The efferent connections of the frontal lobes with subcortical centers may be divided into corticostriate, corticothalamic, and corticohypothalamic connections, and descending connections with the brain stem. The corticostriate fibers originate in the two suppressor areas of the frontal cortex, areas 8 and 24, and terminate in the caudate nucleus (Garol and McCulloch 1944). The corticothalamic fibers from the frontal areas descend to the dorsomedial nucleus. The corticohypothalamic fibers have been studied by Ward and McCulloch (1947) by the method of physiological neuroanatomy. These studies appear to demonstrate that rather specific descending connections exist between different areas of the frontal cortex (and area 64) and different nuclear elements of the hypothalamus particularly the supra-optic and paraventricular nuclei, the lateral and

posterior hypothalamic areas, and the mammillary body. The connections with the paraventricular and supraoptic nuclei are of special significance, for the supraoptic nuclei are known to be connected functionally with the posterior lobe of the pituitary gland by tracts of unmyelinated fibers which descend through the infundibular or pituitary stalk.

HOWARD H. LANDER, M D

Apoplexy N. C. GILBERT and GEZA OK TAKATS. *J Am M Ass.*, 1948, 136: 659

Because of the remarkable stability of the cerebral circulation it is generally accepted that the neurovascular mechanism of the brain is weak. However many transient cerebral disturbances and symptoms cannot be explained except on a vasomotor basis. Vasoconstriction of the cortical vessels and other circulatory disturbances have been demonstrated experimentally in the presence of emboli and cerebral infarction.

The authors have adopted a more active method of treating patients who have undergone cerebral vascular accidents. Apoplexy was differentiated as cerebral hemorrhage, thrombosis, and embolism. The criteria applied for the diagnosis of these three conditions are fully explained and discussed in the original article.

Twenty five patients, 3 of whom had suffered hemorrhage, 12 a thrombosis and 10 an embolism, were treated with cervical sympathetic block. Good responses were noticed in 19 patients, 7 died and 2 showed no improvement. The best responses were obtained in the patients who were treated for embolism. The 3 patients who had suffered of hemorrhage died.

The injections were performed in the region of the stellate ganglion on the affected cerebral side and within the first few hours of the cerebrovascular accident. The improvements were attributed to the block only if they followed immediately the appearance of Horner's syndrome. The duration of improvement varied from a few hours to several days and were maintained in some cases by repeated injections. The most significant improvements were the conversion of flaccid paralysis into spastic paralysis, amelioration of motor and speech functions and regain of consciousness.

As a result of their experience the authors suggest the following therapeutic measures in acute cerebrovascular accidents: (1) in cases of cerebral embolism the oxygen tent slowing of rapid fibrillation stellate block and the administration of anticoagulants (2) in cases of cerebral thrombosis oxygen tent, venesection when hypertension is present stellate block and release of increased spinal fluid pressure (3) in cases of cerebral hemorrhage oxygen tent slow spinal drainage and possible surgical evacuation of clots. In all three types of accidents the intravenous administration of hypertonic sucrose or concentrated albumin solution combined with aminophyllin is given to combat cerebral edema.

GEORGE PERRET, M.D.

Notes on the Pathology of Cranial Tumors. Tumors Originating in the Marrow of the Diploe. CYRIL B. COURVILLE. *Bull Los Angeles Neur Soc.*, 1948, 13: 19.

This article is one of a series which the author has written on various types of tumors of the cranium. The tumors under consideration here are those of the red marrow of the cranial diploe are varied in nature, never common and in some instances they are quite rare.

There are three general types of such intradiploic tumors: (1) interstitial tumors (fibroma, myxoma, and fibromyxoma) which are quite rare; (2) tumors arising from the hemopoietic parenchyma (myeloma, myeloblastic sarcoma, and chloroma), and (3) a group of doubtful origin, such as Hodgkin's disease (lymphogranuloma) and xanthoma. Another tumor now known as Ewing's tumor or reticulosarcoma is usually metastatic, and is only rarely found to be primary in the bones of the calvarium. Multiple myelomas are among the more common tumors in this general family of neoplasms and they may be of the plasma cell or giant cell type. Myeloblastic sarcomas are rare. They are osteoclastic in behavior. Chloromas are a local manifestation of leukemia, and they are usually rapidly fatal. Of course, there is much argument as to whether Hodgkin's disease is a true tumor or not. Xanthomatosis is an unusual disease, occurring most commonly in children and no doubt represents the involvement of the reticuloendothelial system in a disorder of fat metabolism. It is usually accompanied by a triad of symptoms: diabetes insipidus, circumscribed destruction of the flat bones, and exophthalmos indicative of an involvement of all the bones of the skull.

In any of these diploic tumors surgery is usually not very effective. Radiotherapy sometimes exerts a staying action on their progress.

JOHN MARTIN, M D

Angiomas of the Cranial Vault. Report of Cases with Some Remarks as to Their Pathology and Surgical Treatment. CYRIL B. COURVILLE, PHILIP J. VOGLER, and A. J. MURIELLETTA, JR. *Bull Los Angeles Neur Soc.* 1948, 13: 1.

The authors point out that angiomas of the skull (usually occurring in the vault and rarely in the petrous portion of the temporal bone) are but one member of a large family of tumors of angioblastic origin about the head (angioendotheliomas, angioblastic meningiomas, hemangioblastomas) and that they are sufficiently individual and common in nature to warrant special classification. They have their genesis in vasoformative cells which for some reason assume a neoplastic urge, and while they grow at various rates of speed, they are usually considered benign. A local palpable bulge of the cranium is commonly seen, and the roentgenograms will show a thickening of the skull as if the two plates were ballooned apart by an area of tissue only partially calcified and filled with calcific striae. Histologically these tumors consist of a connective tissue stroma in which

many newly formed blood vessels are present. These vessels may be either cavernous or capillary in nature. In the masses of proliferating cells, vacuoles appear which on coalescence form irregular cavities. If the cavities remain large, then a cavernous type of angioma results. If a well defined endothelial lining is formed before coalescence of the spaces takes place, it seems that actual capillaries form.

The authors have collected brief information on 43 instances of such tumor from the literature. They report in some detail the data concerning such a tumor discovered incidentally at the autopsy of one of their patients. They suggest that although the tumor usually does not produce any readily recognized signs or symptoms in the patient it is probably the best surgical judgment to remove them even when they are found inadvertently. The color photograph of the specimen was especially interesting.

JOHN MURPHY, M.D.

Gram-Negative Meningitis following Head Wounds.
WALPOLE LEWIS. *Brit J Surg* 9:5 35 196

An opportunity arose to study the effects of gram-negative organisms in war wounds of the head and spine mainly because of the widespread use of penicillin and the sulfonamides to control infection from gram-positive bacteria. Twenty cases of meningitis caused by gram-negative organisms, especially the *Bacillus coli* are presented as they occurred in 63 head and 160 spinal wounds from Northwest Europe in 1944 and 1945. All wounds were penetrating, and when the dura mater was intact no instance of gram-negative meningitis occurred.

In the series 8 cases were due to the *Bacillus coli*, 3 to the *Pseudomonas pyocyaneus* and 9 to coliform bacilli and Gram-positive organisms. In *Pyocyaneus* meningitis the mortality rate was 100 per cent, and in the others the mortality rate was approximately 50 per cent. A major factor in the recovery of 4 cases was thought to be due to surgical removal of retained foreign bodies and necrotic material. *Coliform* meningitis were usually found early after injury whereas *Pseudomonas pyocyaneus* was a late invader and was usually secondarily introduced.

Case histories, laboratory data, and statistical charts are given in the text. Although streptomycin was not freely available at the time of the clinical study its use in treatment is mentioned in the discussion. The importance of adequate surgical care of penetrating head wounds from the onset is stressed. Considerable space in the discussion is given to the importance of preventing and treating subarachnoid block in pyogenic meningitis. JOHN L. BELL, M.D.

Major Trigeminal Neuralgia. EDWARD W. DAVIS and HOWARD C. NARRINGER. *California M* 9:3, 65 130.

The authors present a statistical analysis of 245 cases of trigeminal neuralgia. The disease had its greatest incidence in the sixth decade. It occurred twice as frequently among females as in males. The right side was involved in 179 cases as compared to

75 cases for the left, but 9 patients had bilateral involvement. The average duration of symptoms before the patients were seen by the authors was 7 years. The pain rarely began in the ophthalmic division. It had its onset in the mandibular and maxillary divisions in equal frequency and often spread to involve adjacent divisions.

Patients describe the pain with striking similarity using such words as "jabbing cutting, burning light stinging or electric-shock-like." Nearly all state that it begins and stops suddenly. There are usually complete remissions of pain of from months to years.

Most patients indicate definite trigger zones, the most common being the lips, gums, nasolabial fold, ala of the nose and the chin. The patients take great care when they laugh, talk, eat, brush their teeth, or wash their face.

Forty-four patients noted residual soreness after or between attacks. Of these 23 had residual soreness for only a short time after the usual lancinating sharp pain, but were relieved by sensory root section or alcohol injection. The remaining 21 had constant pain interspersed with sharp pains but all except one of these responded to treatment. This patient was relieved of the sharp lancinating pain, but the dull constant ache remained.

One hundred and seventy-five patients received alcohol injections. The average alcohol injection was effective for from 6 to 14 months the longest period of relief being 7 years. Neurectomies were done in 3 patients and the results were similar to those following alcohol injections. Sensory root sections by means of the subtemporal approach were done in 179 patients, most of whom had previously had either an alcohol injection or a neurectomy. There were 3 deaths following root section. Thirty-two patients had a temporary facial palsy following root section. When partial section of the root was done, pain appeared later in the area innervated by the undivided portion and required reoperation in 6 of the cases.

Forty-eight patients were given trichlorethylene. Half of them received from partial to complete relief. The inference is made that this method has its chief usefulness in the very old patients who are considered poor operative risks and in whom alcohol injections have been unsuccessful.

The authors conclude that the procedure of choice is a differential section of the sensory root with sparing of the motor root.

DANIEL REED, M.D.

Glossopharyngeal Neuralgia: A Cause of Cardiac Arrest. B. GUNSON S. RAY and HAROLD J. STEWART. *Am. Heart J* 9:3, 35 458.

Glossopharyngeal neuralgia is associated with cardiac arrest, as first reported by Riley and his associates in 1913. The authors call attention to this syndrome, which originates through the carotid sinus reflex. The excessive stimuli to the sinus reflex result from the afferent pathway of the carotid sinus reflex through the glossopharyngeal nerve.

A case is reported of a 40 year old male with characteristic glossopharyngeal pain. With severe attacks cardiac arrest resulted, the blood pressure fell and the patient became pale, lost visual fixation showed signs of confusion and occasionally had complete syncope.

The glossopharyngeal nerve was divided intracranially, which afforded relief from the neuralgia and abolished the episodes of cardiac arrest and syncope.

HOWARD A. BROWN, M.D.

The Role of the Glossopharyngeal Nerve in the Carotid Sinus Reflex in Man; Relief of Carotid Sinus Syndrome by Intracranial Section of the Glossopharyngeal Nerve BROWN S. RAY and HAROLD J. STEWART *Surgery* 1948 23 411

Denervation of the walls of the carotid sinus and of the Y of the common carotid bifurcation has been commonly practiced for relief of the hypersensitive carotid sinus. This operation has met with a fair degree of success but often fails to give relief because of local nerve regeneration or incomplete removal of all the afferent nerve connections.

The four nerves which contribute to the innervation of the carotid sinus and adjacent carotid body are the glossopharyngeal, vagus, cervical sympathetic, and hypoglossal nerves. The glossopharyngeal connections of the carotid sinus nerve transmit the bulk of the cardiovascular components of the sinus reflex in the dog and Bincy raised the question as to the possibility of altering the systemic blood pressure in humans by intracranial section of the glossopharyngeal nerve.

Most observers believe that the carotid sinuses and the aortic arch with their associated carotid and aortic bodies exert a major regulating influence on the central cardiovascular and respiratory control. Stimulation of the sinus by chemical means by increased pressure from within or by direct pressure from without, causes the heart rate to slow the blood pressure to fall and respirations to increase at least until compensated for by other mechanisms.

The syndrome of carotid sinus syncope is well established. Three types of the syndrome have been described: (1) the 'vagal type' resulting from cerebral anoxia due to reflex cardiac astyole, (2) the 'depressor type' resulting from cerebral anoxia due to a fall in systemic blood pressure alone, and (3) the cerebral type in which syncope ensues without marked change in cardiac rate or in blood pressure.

Bincy reports 4 cases and Ray reports 15 in which a temporary rise in blood pressure and cardiac rate followed intracranial division of the glossopharyngeal nerve for relief of pain. In most of the patients the return of blood pressure and cardiac rate to preoperative levels occurred in a few days as the result of compensation notably the contralateral carotid sinus reflex.

One unusual syndrome linking the glossopharyngeal nerve to the carotid sinus reflex is reported—a combined glossopharyngeal tic douloureux and cardiac arrest. In the syndrome, paroxysms of pain in

the region supplied by the glossopharyngeal nerve was accompanied with cardiac slowing or arrest and a fall in blood pressure, and sometimes syncope. Intracranial division of the glossopharyngeal nerve abolishes the entire syndrome.

Ray reports 3 cases in which the ninth nerve was divided intracranially on one side for relief of the carotid sinus syndrome. Two of these patients obtained marked relief of the former attacks of syncope (now 5 years and 3½ years since the operations were performed). Special preoperative tests consisted of pressure over the carotid sinuses with resultant carotid sinus syndrome effects, notably from the hypersensitive side, and procainization of the hypersensitive sinus followed by pressure with resultant loss of hypersensitivity.

Postoperatively pressure over the carotid sinus on the side of the nerve section caused no alteration in cardiac rate, blood pressure or respirations; there is no loss of consciousness as long as pressure does not occlude the internal carotid artery. The carotid sinus on the unoperated side possessed the same degree of sensitivity as that which existed preoperatively.

In one case, intracranial division of the glossopharyngeal nerve on one side and anesthetization of the opposite carotid sinus with procaine sodium cyanide evoked a respiratory reaction in the same time interval from injection as in the control cases with intact sinus mechanisms, thereby raising the question as to whether the chemically induced portion of the carotid sinus reflexes traverse pathways other than the ninth nerve.

The intracranial division of the glossopharyngeal nerve in patients with the carotid sinus syndrome has positively shown that all the effects resulting from pressure on the sinus are transmitted by this nerve since the carotid sinus syndrome appears to be largely due to pressure stimuli. Intracranial division of the glossopharyngeal nerve is an ideal neurosurgical procedure inasmuch as regeneration of the nerve is impossible and local surgery is avoided thus eliminating the danger of injury to the carotid artery.

SPINAL CORD AND ITS COVERINGS

Transperitoneal Approach to the Intervertebral Disc in the Lumbar Area JOHN D. LANE, JR., and EMORY S. MOORE, JR. *Ann. Surg.* 1948, 127 537

According to the authors, the syndrome of low back pain due to alterations in the intervertebral discs although well recognized clinically leaves much desired in its surgical treatment. Numerous articles report instances of the early recurrence of symptoms or only partial help after present surgical procedures. To improve on some of the undesirable features of the current operation transperitoneal approach with or without bone implantation into the intervertebral space after removal of the diseased disc has been devised. The object of such a procedure is

many newly formed blood vessels are present. These vessels may be either cavernous or capillary in nature. In the masses of proliferating cells, vacuoles appear which on coalescence form irregular cavities. If the cavities remain large, then a cavernous type of angioma results. If a well defined endothelial lining is formed before coalescence of the spaces takes place it seems that actual capillaries form.

The authors have collected brief information on 43 instances of such tumor from the literature. They report in some detail the data concerning such a tumor discovered incidentally at the autopsy of one of their patients. They suggest that although the tumors usually do not produce any readily recognized signs or symptoms in the patient it is probably the best surgical judgment to remove them even when they are found inadvertently. The color photograph of the specimen was especially interesting.

Glossopharyngeal Neuralgia: A Cause of Cardiac Arrest. BRONSON S. RAY and HAROLD J. STEWART. *Am. Heart J* 1943, 35, 458.

Glossopharyngeal neuralgia or the *doulooureux* may at times be associated with cardiac arrest, as first reported by Riley and his associates in 1943. The authors call attention to this syndrome, which originates through the carotid sinus reflex. The excessive stimuli to the sinus reflex result from the afferent pathway of the carotid sinus reflex through the glossopharyngeal nerve.

A case is reported of a 40 year old male with characteristic glossopharyngeal pain. With severe attacks, cardiac arrest resulted, the blood pressure fell and the patient became pale, lost visual fixation showed signs of confusion, and occasionally had complete syncope.

The glossopharyngeal nerve was divided intracranially, which afforded relief from the neuralgia and abolished the episodes of cardiac arrest and syncope.

HOWARD A. BROWN, M.D.

The Role of the Glossopharyngeal Nerve in the Carotid Sinus Reflex in Man; Relief of Carotid Sinus Syndrome by Intracranial Section of the Glossopharyngeal Nerve. BROOKS S. RAY and HAROLD J. STEWART. *Surgery* 1948, 23, 411.

Denervation of the walls of the carotid sinus and of the Y of the common carotid bifurcation has been commonly practiced for relief of the hypersensitive carotid sinus. This operation has met with a fair degree of success, but often fails to give relief because of local nerve regeneration or incomplete removal of all the afferent nerve connections.

The four nerves which contribute to the innervation of the carotid sinus and adjacent carotid body are the glossopharyngeal, vagus, cervical sympathetic, and hypoglossal nerves. The glossopharyngeal connections of the carotid sinus nerve transmit the bulk of the cardiovascular components of the sinus reflex in the dog, and Bucy raised the question as to the possibility of altering the systemic blood pressure in humans by intracranial section of the glossopharyngeal nerve.

Most observers believe that the carotid sinuses and the aortic arch with their associated carotid and aortic bodies exert a major regulating influence on the central cardiovascular and respiratory control. Stimulation of the sinus by chemical means by increased pressure from within or by direct pressure from without, causes the heart rate to slow, the blood pressure to fall, and respirations to increase, at least until compensated for by other mechanisms.

The syndrome of carotid sinus syncope is well established. Three types of the syndrome have been described: (1) the "vagal type" resulting from cerebral anoxia due to reflex cardiac asystole, (2) the depressor type resulting from cerebral anoxia due to a fall in systemic blood pressure alone, and (3) the cerebral type in which syncope ensues without marked change in cardiac rate or in blood pressure.

Bucy reports 4 cases and Ray reports 15 in which a temporary rise in blood pressure and cardiac rate followed intracranial division of the glossopharyngeal nerve for relief of pain. In most of the patients the return of blood pressure and cardiac rate to preoperative levels occurred in a few days as the result of compensation, notably the contralateral carotid sinus reflex.

One unusual syndrome, linking the glossopharyngeal nerve to the carotid sinus reflex, is reported—a combined glossopharyngeal tic douloureux and cardiac arrest. In the syndrome, paroxysms of pain in

the region supplied by the glossopharyngeal nerve was accompanied with cardiac slowing or arrest and a fall in blood pressure, and sometimes syncope. Intracranial division of the glossopharyngeal nerve abolishes the entire syndrome.

Ray reports 3 cases in which the ninth nerve was divided intracranially on one side for relief of the carotid sinus syndrome. Two of these patients obtained marked relief of the former attacks of syncope (now 5 years and 3½ years since the operations were performed). Special preoperative tests consisted of pressure over the carotid sinuses with resultant carotid sinus syndrome effects, notably from the hypersensitive side and procainization of the hypersensitive sinus followed by pressure with resultant loss of hypersensitivity.

Postoperatively pressure over the carotid sinus on the side of the nerve section caused no alteration in cardiac rate, blood pressure or respirations; there is no loss of consciousness as long as pressure does not occlude the internal carotid artery. The carotid sinus on the unoperated side possessed the same degree of sensitivity as that which existed preoperatively.

In one case, intracranial division of the glossopharyngeal nerve on one side and anesthetization of the opposite carotid sinus with procaine sodium cyanide evoked a respiratory reaction in the same time interval from injection as in the control cases with intact sinus mechanisms, thereby raising the question as to whether the chemically induced portion of the carotid sinus reflexes traverse pathways other than the ninth nerve.

The intracranial division of the glossopharyngeal nerve in patients with the carotid sinus syndrome has positively shown that all the effects resulting from pressure on the sinuses are transmitted by this nerve since the carotid sinus syndrome appears to be largely due to pressure stimuli. Intracranial division of the glossopharyngeal nerve is an ideal neurosurgical procedure inasmuch as regeneration of the nerve is impossible and local surgery is avoided thus eliminating the danger of injury to the carotid artery.

SPINAL CORD AND ITS COVERINGS

Transperitoneal Approach to the Intervertebral Disc in the Lumbar Area. JOHN D. LANE, JR., and EMORY S. MOORE, JR. *Ann. Surg.* 1948, 127, 537.

According to the authors, the syndrome of low back pain due to alterations in the intervertebral discs although well recognized clinically leaves much desired in its surgical treatment. Numerous articles report instances of the early recurrence of symptoms, or only partial help after present surgical procedures. To improve on some of the undesirable features of the current operation transperitoneal approach with or bone implantation into the intervertebral space after removal of the diseased disc has been devised. The object of such a procedure is

2 To remove completely the pathological disc with the cartilaginous end plates of the adjacent vertebrae.

3 To wedge the disc space open with an ox bone implantation to maintain normal space between the adjacent vertebrae and cause firm bony fusion.

Several undesirable features of the present posterior approach add to the desirability of the new technique. The usual route with hemilaminectomy frequently gives inadequate exposure so that if anterior herniation of the disc has occurred complete visualization is not always possible. In exposure of the disc, retraction of the nerve roots may result in their irritation or permanent damage, hemorrhage from the anterior longitudinal veins often prevents complete visualization and has been found to cause postoperative sequelae by hematoma formation with consequent fibrosis and nerve root adhesions and only a small part of the disc and cartilaginous end plates can be removed through the posterior approach. Because of the removal of the nuclear material without substitution of any other substance, there is narrowing of the disc space with joint instability.

The advantages of the anterior transperitoneal route are listed.

1 There is adequate visualization of the entire disc space and cartilaginous end plates.

2 The third, fourth, and fifth lumbar discs can be examined and treated through the same (abdominal) incision.

3 Removal of the entire disc and cartilaginous end plates to obtain firm bony union can be accomplished.

4 Hemorrhage is easily controlled and does not occur into the spinal canal. Retraction of the nerve roots or cord is not necessary.

5 A large bone implant can be wedged into the disc space to prevent narrowing until fusion between adjacent vertebral bodies has taken place.

The procedure is described as follows.

After the patient is placed in a slight Trendelenburg position, a paramedian incision is made. The redundant portions of the sigmoid colon, cecum and small intestines are displaced into the upper half of the abdominal cavity. The pelvic colon is retracted to the left after the ureters have been identified. An incision is made in the posterior pelvic peritoneum beginning over the sacrum and extending to the bifurcation of the aorta. The kidney bar is now elevated sufficiently to cause hyperextension of the lumbar spine. The fifth disc is located by palpation between the common iliac vessels. The pronsural sympathetic nerve plexus and veins are freed by blunt dissection and retracted laterally which completely visualizes the anterior longitudinal ligament over the prominence of the fifth lumbar disc. A

transverse incision is made across the anterior longitudinal ligament at the lower margin of the fifth vertebra and from the midportion of this a vertical incision is made to the upper margin of the sacrum. These flaps are reflected and the entire contents of

the disc space are removed by a curette until the ligaments retaining the disc are visible. These ligaments are explored and if defects are found, they are further opened to determine if nuclear material has been extruded. If so, this is removed. The cartilaginous end plates are completely excised from the surface of the vertebrae by a chisel or curette.

To maintain the disc space in its normal width while fusion is progressing a specially prepared ox bone wedge is used. The wedge consists of a crescent shaped piece of bone which is driven into the disc space while the spine is hyperextended. Between the wings of the crescent, a large square bone peg is placed. These pieces fill the disc space completely. The flaps of the anterior ligament are closed and sutured over the disc space in normal position.

Exposure of the third and fourth disc spaces is slightly more difficult, but can be accomplished by retracting the ureter to the right, and the vena cava and aorta to the left.

Closure consists of suturing the anterior longitudinal ligaments to adjacent vertebrae, and stitching the posterior peritoneal layers and the various portions of the anterior abdominal wall.

Postoperative care emphasizes combating intestinal distention and phlebitis. No cast or brace is used for 30 days, but the patient is kept supine on a hard surface. Roentgenograms of the lumbar region are then taken and a body cast is applied over the entire lumbar and sacral regions. With this, the patient is permitted to be ambulatory and is sent home. His condition is frequently evaluated with roentgenograms and if the convalescence is satisfactory he is supplied with a lumbosacral belt and advised to avoid strenuous exercise. He returns at monthly intervals for examination.

A diagnosis of herniated nucleus pulposus was made in 97 patients at the Marine Hospital, Baltimore, Maryland. Of these, 36 were subjected to surgery and the procedure described here was used. Among the 36 multiple discs were found in 11. A preliminary survey revealed improvement in 33.

The authors conclude by stating that obliteration of the involved disc spaces by bony fusion is necessary for complete amelioration of the symptoms due to intervertebral disc lesions.

C. FARRINGTON KIRKLE, M.D.

Surgery of Lumbar Intervertebral Disc Protrusion.

MURRAY A. FALCONER, MURRAY McGEORGE, and A. CHARLES BRIDG. *B ILL J Surg* 44:3, 35-5.

From a New Zealand neurosurgical unit 100 consecutive operative cases of protruded lumbar intervertebral disc are analyzed. The case material was divided into two main groups that in which sciatica was the predominant feature, and that in which persistent severe low back pain predominated. The analysis includes discussion of the selection of cases, operative technique, complications, subsequent operations, and results of operative treatment of disc protrusion. The article is well illustrated with numerous photographs of surgical specimens, myelograms,

schematic drawings of the pathosis of protruded intervertebral discs and 11 tables of statistics regarding the results and follow up of the patients.

The criteria for operation in all cases included a failure of at least 1 month's complete rest to relieve symptoms of sciatica or of low back pain. A positive myelogram in patients with severe low back pain alone was a factor necessary before operation was considered. However a normal myelogram in patients with severe intractable sciatica did not influence the decision to operate.

The authors did not limit their exposure to the interlaminar approach but performed a laminectomy bilateral if necessary whenever difficulty was encountered in obtaining proper exposure. Sixty-one of the 100 patients had a laminectomy. Spinal fusion is mentioned only in that it prolongs the convalescence and does not add appreciably to the good results of surgery for protruded intervertebral disc.

Two points regarding the positioning of patients for the operation are noted. To reduce the engorgement of the dural and extradural venous plexuses, it is advised to place sandbags under the groins and a pillow under the chest of the patient which will remove all pressure from the abdomen. When concealed or intermittent protruding discs are suspected, it is advised to hyperextend the patient's hips and spine while he is on the operating table as this maneuver will frequently bring the disc into view.

Although patients were kept in bed for 3 weeks during the postoperative period the authors stress the importance of back exercises in the convalescence. Exercises are started in bed on the tenth day and gradually increased throughout the period of rehabilitation. Usually a patient was ready to assume light work from 2 to 4 months after operation. From 4 to 6 months was required before a patient could resume heavy labor.

Fourteen of 100 patients were reoperated upon one or more times as symptoms due to inadequate removal of the disc continued after operation. Because of the degenerative changes occurring in other intervertebral discs and associated derangements of the intervertebral joints complete cure is not possible in all cases.

JOHN L. BELL, M.D.

PERIPHERAL NERVES

Brachial Neuralgia W. RUSSELL BRAIN *Lancet* Lond., 1948 1: 393.

Most lesions of the cervical spinal nerves are partial and do not affect all forms of sensibility equally or all parts of the dermatome to the same extent. Subjective sensory disturbances are more common than objective sensory loss and more prominent than motor symptoms. According to the author the palmar surface of the thumb and index finger is included in the distribution of the sixth cervical dermatome the middle finger in the seventh, and the ring and little fingers in the eighth cervical dermatomes. He found that the dorsal aspect of the shoulder receives innervation from C7 and that

irritation of this spinal nerve causes pain to be referred to the shoulder and may cause pain and deep tenderness in the majority of the shoulder muscles which are innervated by its fibers.

The author discusses briefly the principal causes of brachial neuralgia and examines their symptoms and points of differential diagnostic interest. Brachial neuralgia may be caused by cervical spondylitis as a result of loss of intervertebral disc space or osteophytic outgrowths, and produces pain in the distribution of the sixth and seventh cervical nerves. Herniation of a cervical intervertebral disc most often of the seventh cervical, produces considerable pain in the neck, which is often not present in cervical spondylitis although the roentgenographic abnormalities are more striking. The costoclavicular syndromes may be produced by 14 different abnormalities involving the root of the neck: an abnormal seventh cervical transverse process, a fibrous band from the seventh transverse process to the first rib, a cervical rib, a first rib of abnormal shape, an unusually high first rib, a cervicodorsal scoliosis, an abnormal origin of the scalenus medius, an abnormal insertion of the scalenus medius, a hypertrophy or spasm of the scalenus anticus, an abnormal origin or insertion of the scalenus anticus, the passage of neurovascular structures through the substance of the scalenus anticus, loss of power or tone in the elevators of the shoulder girdle allowing the inner cord of the brachial plexus to impinge on a normal first rib and costoclavicular compression. The syndromes may be conveniently divided into those with and those without structural abnormalities. The latter group is more difficult to diagnose. One form, known as acroparesthesia, common in middle-aged women is thought to be of vascular origin and to be caused by weight carrying. It is characterized by awakening at night with tingling in one or more commonly both hands. The author has treated such cases successfully with vasodilators and found small doses of trinitrin and thyroid extract very effective. Most of the other cases of costoclavicular disturbances should be treated by exercises of the shoulder shrugging type as long as the symptoms and signs are purely sensory but when muscular atrophy or vasomotor symptoms are present surgical treatment is indicated.

Another cause of brachial neuralgia is the compression neuritis of the median nerve in the carpal tunnel often produced by fractures or other structural abnormalities of the lower end of the radius or of the proximal carpal bones. It produces sensory and muscular disturbances in the distribution of the median nerve. Treatment consists in immobilization or decompression of the swollen nerve in the carpal tunnel. It is occasionally followed by a Raynaudlike syndrome. Spinal tumors only rarely produce pain simulating a brachial neuralgia but produce other definite signs and symptoms.

The author stresses the importance of a thorough clinical examination and the great value of roentgenographic studies.

GEORGE PERREY, M.D.

SYMPATHETIC NERVES

Serious Accidents Occurring with Infiltration of the Stellate Ganglion (Les accidents graves de l'infiltration tellaire) G. ARNDT *Rev. chir. Par.* 94:5 67-73.

Although infiltration of the stellate ganglion according to the author is definitely indicated for numerous conditions, several complications occur

1. Fatal accidents. The author describes 12 cases in which death occurred because of infiltration of the stellate ganglion. Three deaths occurred in patients with angina pectoris, 7 in patients with acute asthma,

death took place in a patient with a malignant tumor in the cervical region, and another in a patient with chronic arachnoiditis. Ten of these patients (those with the heart and asthma conditions) were poor risks when they first presented themselves. According to Danielopolu infiltration of the stellate ganglion is dangerous in patients with angina pectoris because it paralyzes the sensory fibers of the heart and suppresses the anginal pain which is supposed to act as a "warning signal." This conclusion is not supported by the author.

Most important is the danger of injection of the anesthetic into the vertebral canal which produces a cervical or medullary anesthesia and subsequent death. It is necessary before any anesthetic agent is injected that one is certain that the cerebrospinal fluid cannot be withdrawn.

2. Pulmonary accidents. The chief complication here is the production of a pneumothorax which, although not particularly serious, is painful for the patient.

3. Medullary accidents. These accidents are attributed to injection of the anesthesia into the cerebrospinal fluid and may be due to an idiosyncrasy to the agent used. However this view is not supported by the wide usage of novocaine elsewhere in the body. Such deaths are probably the result of a paralysis of the central nervous system at these levels.

4. Nerve accidents. Damage to the laryngeal nerve and brachial plexus has been reported from technical errors in placement of the needle.

The following suggestions are given by the author to avoid complications during injection of the stellate ganglion.

The transverse vertebral process is used as a point of reference and the superior external approach is considered the best. Before injection of the anesthetic it is mandatory to aspirate the syringe to determine if reflux of blood or cerebrospinal fluid occurs. If such does occur the location of the needle should be changed.

The author concludes by stating that indications for injection of the stellate ganglion should not be reduced because of possible complications but, rather more rigorous attention should be paid to the technique of this procedure.

SURGERY OF THE THORAX

CHEST WALL AND BREAST

Management of Breast Tumors—An Analysis of 336 Cases. JOHN A. WOLFE and WALTER W. CARROLL. *Q. Bull. Northwest. Univ. M. School* 1948, 22: 86.

Of the 336 patients whose cases are reported 170 had carcinoma, while the remainder (6 of whom had multiple tumors) presented benign lesions. The malignant group was essentially of 2 types: scirrhous carcinoma (88) and adenocarcinoma (58). The benign specimens presented 2 large main groups: the freely moveable adenomas (44) and the somewhat imbedded tumors with varying stages of cystic dysplasia (95).

In age the patients ranged from the early teens to the eighties. Those in the fourth decade showed a preponderance of benign tumors while those in the sixth showed a preponderance of malignant tumors.

A history of breast pain or tenderness in the tumor was quite constant in the benign tumors while the absence of pain was characteristic of the malignancies.

An even distribution of tumors between breasts may be expected but the upper outer quadrant presents more disease of malignant, as well as of benign type than any other equally sized area of the breast.

The diagnostic significance of nipple discharge in its relationship to malignancy has been overrated. Papillary carcinoma is the only logical type of malignant tumor to be accompanied by bleeding from the nipple.

The primary malignant mass is usually stony hard and fixed in the breast substance. As the malignant tumor grows a replacement phenomenon accompanied by the production of contracting scar tissue occurs. As the fibrous septa connecting with the skin become involved and secondarily pulled out of alignment, the overlying skin will be retracted inwardly to form a slight dimple. The presence of a dimple is the earliest of the retraction signs. As the tumor grows to involve more of the subcutaneous tissue, the overlying skin may actually be retracted and fixed.

Palpable axillary nodes are to be regarded with suspicion but their absence is not of diagnostic value. It has been found that in cases of proved cancer of the breast, with preoperatively palpable nodes, the incidence of negative nodes was 32 per cent, while in patients with no palpable nodes the incidence of positive nodes was 29 per cent. In the series reported the incidence of positive nodes was 54 per cent.

Microscopic identification following surgical removal is the only accurate method of diagnosis.

SAMUEL KAHN, M.D.

The Use of Male Hormones in the Treatment of Cancer of the Female Breast (*L'utilisation des hormones mâles dans le traitement du cancer du sein chez la femme*) ANDRÉ SICARD. *Presse méd.*, 1948 56: 149.

The influence of ovarian secretion on breast cancer is recognized both experimentally and clinically. One may combat cancer of the breast by castration either surgically or by irradiation by the administration of androgenic substances or by a combination of these methods.

The author relates his experiences with 18 patients who had cancer of the breast with metastases, most of which were osseous. Two were treated with androgenic substances alone while the remainder were subjected to either surgical or irradiation castration and in addition were given androgens. The growth of all the metastases was checked, all of the patients were relieved of pain and their general condition was improved to such an extent that they were able to live almost normal lives.

It is upon the metastases that the effect of castration is most marked. However, the immediate results from ovarian castration as the sole procedure are quite unpredictable and there is a marked variability in the duration of relief from pain. These phenomena are probably due to estrogenic activity in other locations in the body. In the postmenopausal female as in the castrated animal one may find estrogenic hormones in both the blood and urine. The estrogenic substances may arise from the adrenal hypophysis, the thyroid, or perhaps the thymus glands. At any rate, the source is a problem of endocrine physiology which has not yet been solved.

The diminution of estrogenic secretion by castration alone is only temporary and incomplete. Because of this fact, the author suggests the use of androgenic substances which combat the effect of all estrogenic substances regardless of their source. Many have hesitated to use hormone therapy as a complementary form of treatment immediately following radical breast resections but rather reserve its use for advanced inoperable cases. The author condemns this point of view and suggests that androgenic substances be used in those cases which are operable as an adjunctive form of therapy.

The use of large doses of testosterone to reach a total of from 3,000 to 4,000 mgm. is indicated during the period of treatment, which in most cases lasts about 3 months. Large doses give more rapid and more lasting relief from pain. The appetite is increased and the bony lesions are recalcified. The substance is administered by pellet implantation and reinforced by three weekly intramuscular injections until the desired dosage and effect are reached. The hormone therapy is discontinued before masculinization becomes too marked.

ORVILLE F. GRIMES, M.D.

Evaluation of Skin Grafting in the Technique of Radical Mastectomy in Relation to Function of the Arm. CHARLES G. NEUMANN and HARRIS CORWAY. *Surgery* 94:8, 3 584

A study of 308 patients operated upon for carcinoma of the breast is presented. The investigation was primarily conducted in an attempt to evaluate the function of the arm following radical mastectomy. The technique of resection was similar in all cases, but there was variation in the type of closure. In 95 cases the wounds were closed primarily. In 131 a small skin graft was used, and in 59 a large skin graft was necessary to cover the defect on the chest wall. Closure with a small skin graft was followed by full function of the arm in the highest percentage of cases. The use of postoperative radiation regardless of the type of closure of the wound was associated with an increased number of patients who showed poor function of the arm.

Statistics are presented which show that closure of the wound of radical mastectomy with a skin graft provides full function of the arm in a greater number of cases than when simple linear closure is used. The use of the skin graft preserves the elasticity of the lateral cutaneous flap which normally allows for full abduction of the arm. ORVILLE F. GRIMES, M.D.

TRACHEA, LUNGS, AND PLEURA

Surgical Treatment of the Solitary Lung Metastasis. DONALD B. ESSLER and BRIAN BLADES. *J. Thorac. Surg.* 94:5, 1 7

Excisional therapy of the solitary lung metastasis is indicated when the primary tumor has been extirpated and when careful search reveals no manifestation of extension other than the solitary metastasis. Metastases have been known to regress and disappear following removal of a primary renal carcinoma. This is an interesting and little understood phenomenon, but it should not be considered a contraindication of surgery for the solitary metastasis.

A solitary metastasis may appear early or very late as long as 10 years after removal of the primary tumor. It is difficult to understand why the development of the late metastasis is delayed. It is reasonable to assume, however, that the chance for a cure in excision of the solitary metastasis is better when the metastasis appears late.

SAMUEL KARR, M.D.

Bronchial Carcinoma Presenting as Polyneuritis. R. WYBURN-MASON. *Lancet* Lond., 948 1 203.

Three cases of polyneuritis complicating bronchial carcinoma are described. In each case the pulmonary symptoms were in abeyance and the patient sought aid for neuritic symptoms.

The patients were men aged 53, 59, and 71 years respectively. In 2 cases the right lung and in one case the left lung was affected. In 2 cases the tumors were comprised of small round cells, and in the third case the tumor was made up of "oat cells." The

cerebrospinal fluid in 2 cases was normal, whereas in the third case it contained 100 mgm. of protein per 100 ml. The course of these cases, from the onset of symptoms to death, ranged from 5 to 14 months.

The etiology of the polyneuritis is discussed and it is concluded that this condition is the result of a nervous reflex from the lung.

JOHN J. MALONEY, M.D.

Progress in Bronchology. LOUIS H. CLEGG. *J. Am. Med. Ass.* 94:8 126 735.

Bronchoscopy is now employed as an aid either in diagnosis or in treatment of practically all bronchopulmonary diseases associated with bronchial obstruction or with an increase of bronchial secretions.

In bronchogenic carcinoma, bronchoscopic biopsy yields a positive diagnosis in from 60 to 80 per cent of the cases. Positive bronchoscopic diagnoses, however, give too few opportunities for successful surgical extirpation of the tumor. It is evident that, in order to treat the disease successfully, it is necessary to make the diagnosis earlier, before large bronchi are obstructed. With the aid of collection tubes and aspirators, secretions may be secured bronchoscopically from the site of the suspected carcinoma, and the cells studied. In cases in which the lesions are beyond bronchoscopic vision, the diagnosis can often be established by this means. Complete surgical removal can then be carried out in a higher percentage of the patients with bronchial carcinoma because of the field of bronchoscopic vision, than of those in whom the lesion is diagnosed by bronchoscopic biopsy.

Many patients with endobronchial benign tumors have been successfully treated by instrumental removal and diathermy bronchoscopically. Adenoma often occurs as an endobronchial or extrabronchial tumor and it may undergo cancerous changes. Surgical extirpation, therefore, must be considered in its treatment.

In the treatment of pulmonary abscess prophylactic measures, sulfonamides and antibiotic drugs, as well as surgery, have turned the trend away from bronchoscopy. It remains a valuable diagnostic aid, however, in cases of suspected bronchial obstruction complicated by pulmonary abscess.

Bronchoscopy still has a definite place in the medical management of patients with bronchiectasis who are not suitable for surgical treatment. It is also of value in the medical preoperative and postoperative care of the surgical group.

In bronchial asthma, the bronchologist must often investigate the tracheobronchial tree to rule out conditions that stimulate asthma and to remove secretions from the air passages. In status asthmaticus, one of the most common causes of death is the blocking of the larger air passages by thick, tenacious secretion. When medical methods fail to remove these secretions, their mechanical removal by bronchoscopic aspiration is often necessary to relieve the marked dyspnea. Bronchoscopic or catheter aspiration also has a definite place in the medical

management of postoperative conditions in which the secretions cannot be coughed up from the air passages.

Routine diagnostic bronchoscopic examination of all tuberculous patients shows an incidence of tuberculous tracheobronchitis in about 10 per cent. Direct inspection is indicated as a diagnostic procedure in cases of pulmonary disease in which the diagnosis has not been definitely established. This includes the large group of cases of obscure chronic cough, hemoptysis and wheezing respiration as well as those with unexpected roentgenographic findings and physical signs. When there is doubt whether bronchoscopy should or should not be done in any case of pulmonary disease it should be done provided there are no contraindications.

SAMUEL KAHN M.D.

An Experimental Study of the Effect of Ligation of Pulmonary Veins in the Dog HENRY SWAN and R. M. MULLIGAN *J. Thorac. Surg.*, 1948, 17, 44.

These experiments were conducted specifically to study the changes resulting from interruption of the venous outflow from the lungs. The authors did not find the answer to this question in any previous publication.

Dogs were utilized and the operative stages were carried out under strict asepsis. The pulmonary vein was doubly ligated and severed. In 11 dogs the veins to the right upper lobe were so treated and in 2 dogs the veins supplying the entire lung were ligated. The only deaths (3) in the first group of dogs occurred in animals which underwent additional though unrelated operative alterations or were under the effect of dicumarol. The other 8 dogs survived from 23 to 134 days when they were sacrificed. Both dogs in the second group which underwent total venous ligation died within 3 days. The authors concluded that death under these circumstances was an expression of the extent of involvement and possibly was based on the blood loss incurred.

Having sacrificed the animals at varying lengths of time postoperatively the authors believed they could trace the sequence of events taking place within the lobe. The first reactions in the lobe include a fibrous or fibrinopurulent pleuritis with adhesions of the lobe to the parietal pleura. The lobe is pumped full of blood by the intact arteries to it. Consequently severe hyperemia, hemorrhage and edema are noted involving especially the alveoli, alveolar ducts and bronchioles. Along with the reduced vitality of the pulmonary parenchyma bronchopneumonia becomes an accompanying reaction. As a result of the ligation thrombosis occurs in the veins to the lobe.

The process of recovery from these acute changes includes the establishment of adhesions between the visceral and parietal pleura through organization of the acute pleuritis. Along with this reaction blood monocytes coming into the arteries migrate from the alveolar capillaries into the alveoli and alveolar ducts and pick up cell debris. Granulation tissue

grows out into the alveoli, alveolar ducts and bronchioles to organize contained exudate. In addition air is evidently resorbed from some alveoli and alveolar ducts. Widespread atelectasis results from the emptying of the contents of these structures by both the scavenging of the hemorrhagic and inflammatory debris and the resorption of edema fluid and residual air. As the collateral blood supply established by the pleural adhesions becomes more abundant in the later stages the still intact arterial blood vessels are able to vascularize the lobe, especially the alveolar capillaries and the still intact bronchial tree is able to admit air for the re-expansion of the lobe. The atelectatic areas then largely disappear the re-expansion beginning first at the periphery of the lobe and then extending centrally. The granulation tissue within the alveoli, alveolar ducts and bronchioles is either resorbed or incorporated into the interstitial fibrous connective tissue.

The final result after 3 or 4 months is a lobe at least 80 per cent re-expanded and apparently functioning with residual vascularized pleural adhesions and focal interstitial fibrosis and hemosiderosis. The thrombi in the proximal ends of the severed veins to the lobe become organized and the veins are recanalized to different degrees.

HIRAM T. LANGSTON M.D.

A Hitherto Unrecognized Tendency to the Development of Widespread Pulmonary Vascular Obstruction in Patients with Congenital Pulmonary Stenosis (Tetralogy of Fallot) AXWOLD R. RICH. *Bull. Johns Hopkins Hosp.*, 1948, 82, 389.

Pulmonary vascular obstruction was found in 90 per cent of 21 consecutive cases of tetralogy of Fallot. The obstruction in question results from widespread focal thrombosis of pulmonary vessels of microscopic size. Both arteries and veins are involved. Frequently the wall of the affected vessel is altered beyond recognition during the process of organization of the thrombus. Every stage is present from the formation of fresh thrombi to the organization and recanalization of the older ones, and it is clear that the process is often a progressive one. It is especially emphasized that the thrombi in these cases tend to occur profusely throughout both lungs.

The thrombi do not result from the operative procedure. The lesions are found not only in patients who have died without operation but also completely organized and recanalized thrombi can be found in patients who expired on the operating table or within a few hours after the procedure designed for the relief of the effects of pulmonic stenosis.

There is no evidence that the arterial thrombi represent emboli from extrapulmonary sites. No thrombi were found in the hearts and in cases of other types in which thrombi in the heart or systemic veins serve as the source of pulmonary emboli diffuse obstruction of minute pulmonary vessels is not encountered. Study of the other viscera in these cases disclosed no diffuse thrombosis, as was found in the lungs.

Evaluation of Skin Grafting in the Technique of Radical Mastectomy in Relation to Function of the Arm. CHARLES G. KUDAMAK and HERBERT CONWAY SURGERY 948, 3 584

A study of 308 patients operated upon for carcinoma of the breast is presented. The investigation was primarily conducted in an attempt to evaluate the function of the arm following radical mastectomy. The technique of resection was similar in all cases, but there was variation in the type of closure. In 95 cases the wounds were closed primarily. In 131 a small skin graft was used, and in 59 a large skin graft was necessary to cover the defect on the chest wall. Closure with a small skin graft was followed by full function of the arm in the highest percentage of cases. The use of postoperative radiation regardless of the type of closure of the wound was associated with an increased number of patients who showed poor function of the arm.

Statistics are presented which show that closure of the wound of radical mastectomy with a skin graft provides full function of the arm in a greater number of cases than when simple linear closure is used. The use of the skin graft preserves the elasticity of the lateral cutaneous flap which normally allows for full abduction of the arm. ORVILLE F. GRUBBS, M.D.

Complete surgical removal can then be carried out in a higher percentage of the patients with bronchial carcinoma beyond the field of bronchoscopic vision, than of those in whom the lesion is diagnosed by bronchoscopic biopsy.

Many patients with endobronchial benign tumors have been successfully treated by instrumental removal and diathermy bronchoscopically. Adenomas often occur as an endobronchial or extra-bronchial tumor and it may undergo cancerous changes. Surgical extirpation, therefore, must be considered in its treatment.

In the treatment of pulmonary abscess, prophylactic measures, sulfonamides, and antibiotic drugs as well as surgery have turned the trend away from bronchoscopy. It remains a valuable diagnostic aid, however, in cases of suspected bronchial obstruction complicated by pulmonary abscess.

Bronchoscopy still has a definite place in the medical management of patients with bronchiectasis who are not suitable for surgical treatment. It is also of value in the medical preoperative and postoperative care of the surgical group.

In bronchial asthma the bronchologist must often investigate the tracheobronchial tree to rule out conditions that simulate asthma and to remove secretions from the air passages. In status asthmaticus, one of the most common causes of death is the blocking of the larger air passages by thick, tenacious secretion. When medical methods fail to remove these secretions, their mechanical removal by bronchoscopic aspiration is often necessary to relieve the marked dyspnea. Bronchoscopic or catheter aspiration also has a definite place in the medical

management of postoperative conditions in which the secretions cannot be coughed up from the air passages.

Routine diagnostic bronchoscopic examination of all tuberculous patients shows an incidence of tuberculous tracheobronchitis in about 10 per cent. Direct inspection is indicated as a diagnostic procedure in cases of pulmonary disease in which the diagnosis has not been definitely established. This includes the large group of cases of obscure chronic cough, hemoptysis, and wheezing respiration as well as those with unexpected roentgenographic findings and physical signs. When there is doubt whether bronchoscopy should or should not be done in any case of pulmonary disease it should be done provided there are no contraindications.

SAMUEL KAHN, M.D.

An Experimental Study of the Effect of Ligation of Pulmonary Veins in the Dog. HENRY SWAN and R. M. MULLIGAN. *J. Thorac. Surg.*, 1948, 17, 44.

These experiments were conducted specifically to study the changes resulting from interruption of the venous outflow from the lungs. The authors did not find the answer to this question in any previous publication.

Dogs were utilized and the operative stages were carried out under strict asepsis. The pulmonary vein was doubly ligated and severed. In 11 dogs the veins to the right upper lobe were so treated and in 2 dogs the veins supplying the entire lung were ligated. The only deaths (3) in the first group of dogs occurred in animals which underwent additional though unrelated operative alterations or were under the effect of dicumarol. The other 8 dogs survived from 33 to 134 days when they were sacrificed. Both dogs in the second group which underwent total venous ligation died within 3 days. The authors concluded that death under these circumstances was an expression of the extent of involvement and possibly was based on the blood loss incurred.

Having sacrificed the animals at varying lengths of time postoperatively the authors believed they could trace the sequence of events taking place within the lobe. The first reactions in the lobe include a fibrinous or fibrinopurulent pleuritis with adhesions of the lobe to the parietal pleura. The lobe is pumped full of blood by the intact arteries to it. Consequently severe hyperemia, hemorrhage and edema are noted involving especially the alveoli, alveolar ducts and bronchioles. Along with the reduced vitality of the pulmonary parenchyma bronchopneumonia becomes an accompanying reaction. As a result of the ligation thrombosis occurs in the veins to the lobe.

The process of recovery from these acute changes includes the establishment of adhesions between the visceral and parietal pleura through organization of the acute pleuritis. Along with this reaction blood monocytes coming into the arteries migrate from the alveolar capillaries into the alveoli and alveolar ducts and pick up cell debris. Granulation tissue

grows out into the alveoli, alveolar ducts and bronchioles to organize contained exudate. In addition air is evidently resorbed from some alveoli and alveolar ducts. Widespread atelectasis results from the emptying of the contents of these structures by both the scavenging of the hemorrhagic and inflammatory debris and the resorption of edema fluid and residual air. As the collateral blood supply established by the pleural adhesions becomes more abundant in the later stages the still intact arterial blood vessels are able to vascularize the lobe especially the alveolar capillaries, and the still intact bronchial tree is able to admit air for the re-expansion of the lobe. The atelectatic areas then largely disappear, the re-expansion beginning first at the periphery of the lobe and then extending centrally. The granulation tissue within the alveoli, alveolar ducts and bronchioles is either resorbed or incorporated into the interstitial fibrous connective tissue.

The final result after 3 or 4 months is a lobe at least 80 per cent re-expanded and apparently functioning with residual vascularized pleural adhesions and focal interstitial fibrosis and hemosiderosis. The thrombi in the proximal ends of the severed veins to the lobe become organized and the veins are recanalized to different degrees.

HIRSH T. LANCASTON, M.D.

A Hitherto Unrecognized Tendency to the Development of Widespread Pulmonary Vascular Obstruction in Patients with Congenital Pulmonary Stenosis (Tetralogy of Fallot). ARNOLD R. RICH. *Bull. Johns Hopkins Hosp.*, 1948, 81, 389.

Pulmonary vascular obstruction was found in 90 per cent of 21 consecutive cases of tetralogy of Fallot. The obstruction in question results from widespread focal thrombosis of pulmonary vessels of microscopic size. Both arteries and veins are involved. Frequently the wall of the affected vessel is altered beyond recognition during the process of organization of the thrombus. Every stage is present, from the formation of fresh thrombi to the organization and recanalization of the older ones and it is clear that the process is often a progressive one. It is especially emphasized that the thrombi in these cases tend to occur profusely throughout both lungs.

The thrombi do not result from the operative procedure. The lesions are found not only in patients who have died without operation, but also completely organized and recanalized thrombi can be found in patients who expired on the operating table or within a few hours after the procedure designed for the relief of the effects of pulmonary stenosis.

There is no evidence that the arterial thrombi represent emboli from extrapulmonary sites. No thrombi were found in the hearts and in cases of other types in which thrombi in the heart or systemic veins serve as the source of pulmonary emboli diffuse obstruction of minute pulmonary vessels is not encountered. Study of the other viscera in these cases disclosed no diffuse thrombosis, as was found in the lungs.

Both polycythemia and the inadequate pulmonary blood flow resulting from pulmonary stenosis favor the spontaneous thrombosis in the pulmonary tree noted in these patients. Whether the increased peripheral resistance in the pulmonary circulation in cases with widespread obstructive thrombosis of the pulmonary vascular bed places an additional burden upon the abnormal heart following the surgical procedure can hardly be answered on the basis of present information.

ORVILLE F. GRIMES, M.D.

Medical Treatment of Acute and Chronic Pulmonary Abscesses. DAVID T. SMITH. *J. Thorac. Surg.* 1948, 7, 72.

Lung abscess, as represented by collected reports has carried a rather poor prognosis. The 34 per cent mortality rate has not been generally improved during the last 10 years although in certain clinics, in which emphasis on the surgical aspect of the disease has been made, rates as low as 2.6 per cent are recorded.

The prognosis in lung abscess depends upon many factors, such as the type of abscess whether single or multiple, whether complicated by bronchiectasis, the inhalation of material with or without irritating substances, and whether or not it is the result of vascular accidents such as thrombosis or infarction. Some evidence seems to point to a more favorable prognosis in abscesses which follow surgical procedures such as tonsillectomy, etc.

The type of bacterial infection is discussed at some length. In the nonputrid pyogenic abscess best results seem to indicate treatment by sulfonamides and penicillin, with resection if adequate improvement does not occur. In fusospirochetal abscesses, early diagnosis is important and treatment with penicillin, with or without arsenicals, sulfonamides, and streptomycin should be instituted promptly. Steady clinical and roentgenological improvement must be obtained by this approach within 6 weeks. If not these abscesses should be subjected to surgery.

The basic treatment of lung abscess includes bed rest and supportive treatment. Early institution of this regimen demands prompt diagnosis. To this must be added drainage regardless of the stage of disease, underscoring the fact that drainage can be secured by medical means such as posturing, and need not imply surgical intervention.

Bronchoscopy aside from ruling out important etiologic factors such as neoplasm or foreign body may well improve such drainage.

Anteal therapy has been variously appraised as to its effectiveness. The best results have been obtained during the first 10 days of disease while the process was still in its pneumonic phase and necrosis was not appreciable. The author has previously reported 60 per cent cures.

Sulfonamide therapy was more effective in the pyogenic (gram positive cocci) rather than in the fusospirochetal abscesses.

Penicillin is probably the most effective single agent in the treatment of lung abscess.

When the abscess has entered a chronic phase medical treatment can hardly be successful. However, a case is reported in detail in which adequate surgical treatment was refused by the patient. The use of sulfonamides, neomarsphenamine desensitization by autogenous vaccine and potassium iodide over a period of 14 months eventuated in an acceptable clinical result, although roentgenological signs persist.

The statistical material submitted is based on reports collected from the literature and supplemented by data from 155 cases seen at Duke Hospital Durham North Carolina from 1940 to 1945 inclusive.

The generally gloomy picture presented for lung abscess is attributed to failure to recognize early lesions in the pre-abscess phase to clearly differentiate the type, and consequently a failure to institute appropriate therapeutic measures. Likewise, the limitations of medical treatment are not appreciated and surgical intervention is delayed beyond the indicated time.

HIRSH T. LAWSON, M.D.

Arteriovenous Fistula of the Lung. HERBERT C. MAIER, AARON HENKELSTEIN, RICHARD J. RILEY and JOSEPH J. BURKE. *J. Thorac. Surg.* 1948, 7, 3.

Cavernous hemangioma of the lung may result in a pulmonary arteriovenous fistula, with the development of cyanosis, polycythemia and clubbing of the extremities but these signs are absent in those pulmonary hemangiomas which do not result in a significant degree of shunt between the pulmonary artery and vein.

A case of arteriovenous fistula of the lung with superimposed bacterial endarteritis is reported. The patient was successfully treated with parenteral penicillin followed by surgical removal of the involved portion of the lung.

The physiological alterations produced by an arteriovenous fistula in the peripheral and pulmonary circulation are compared. A peripheral arteriovenous fistula causes an increase in all elements of the blood volume proportionately an increase in cardiac output, and dilatation of the heart. In contrast, a pulmonary arteriovenous fistula increases only the red cell mass, and has little or no effect on cardiac output and cardiac dynamics.

SAMUEL KAHN, M.D.

Adenoma of the Bronchus. Review of 15 Cases. LAZARO LANGER and EMIL A. NACLERIO. *Am. J. Surg.* 1948, 75, 532.

Bronchial adenoma is a definite clinical and pathologic entity which accounts for about 80 per cent of benign bronchogenic growths. No unanimity of opinion exists regarding its histologic origin, potential malignancy relationship to cancer of the bronchus, and treatment. If the criteria for carcinoma—invagination of adjacent tissue, involvement of regional lymph nodes, and metastasis to distant organs—are accepted it must be concluded that some of the

bronchial adenomas fulfill all the requirements of malignancy. Aside from its potential malignancy the tumor eventually produces sequelae incident to bronchial obstruction—obstructive emphysema, bronchiectasis, total atelectasis, chronic pneumonitis, pulmonary abscess, and empyema.

In the early stages adenoma is usually asymptomatic although a dry cough may be present. Hemoptysis is a cardinal symptom; it is often profuse and is as sudden in its termination as in its onset. As the tumor encroaches upon the lumen of the bronchus symptoms of partial or complete obstruction may appear. A localized wheeze may be noticed. Dyspnea is common. Episodes of pneumonia characterized by cough, mucopurulent sputum, fever, and chest pain occur. As the tumor progresses filling the lumen of the bronchus obstructive effects with irreparable damage to the lung develop as in carcinoma, so that the clinical picture is then one of either atelectasis, bronchiectasis, lung abscess, or empyema.

A plain roentgenogram may present evidence of the existence of the tumor especially related to the secondary effects caused by obstruction. The tumor itself is demonstrated only occasionally. Bronchography may with reasonable accuracy outline the typical cap-shaped defect in the bronchus. Bronchoscopy is the most helpful diagnostic procedure available. The tumor almost invariably arises in the major bronchi and is easily accessible to biopsy and histologic study. The mobile polypoid, soft, smooth, pinkish rounded mass seen protruding into the bronchial lumen is typical. Ulceration is rarely seen.

Exploratory thoracotomy should never be delayed when other diagnostic methods have failed to substantiate the diagnosis of adenoma.

Histologically bronchial adenoma is characterized by the rarity of mitotic figures, the tendency for the cells to be grouped, and the uniformity of the cell type. The cells are small and cuboid; they contain a dark nucleus. They are grouped in a variety of patterns which may be alveolar, columnar, or mosaic in type, according to the arrangement of the stroma which divides the cells into groups.

The methods of treatment of bronchial adenoma are three: (1) radiation therapy, (2) bronchoscopic treatment including (a) implantation of radon seeds, (b) electrocoagulation, and (c) forceps removal, and (3) surgical extirpation, lobectomy, or pneumonectomy. Surgical removal is the treatment of choice.

Fifteen cases of bronchial adenoma cured by pulmonary resection, 10 cured by pneumonectomy and 5 by lobectomy, are reported. SAMUEL KAMR, M.D.

The Clinical Picture of Encapsulated Empyema with Special Consideration of the Complications (Das klinische Bild der Empyemathoraxen mit besonderer Berücksichtigung der Komplikationen). *Deut. med. Wochschr.*, 1947, 72: 665.

The central theme of this article concerns the serious complication resulting from long standing empyema cavities. Sixty patients with encapsulated

empyemas were treated after having spent from 5 months to 3 years in other hospitals, where either a correct diagnosis had not been made or treatment had been inadequate. Over 80 per cent of the patients had empyemas resulting from war wounds of the chest, most of which were complicated by injuries to the abdomen, neck, or both.

A severe state of malnutrition was noted in most of the patients. The authors do not hesitate to mention that the inanition frequently resulted from lack of recognition of the underlying disease process even though some patients were hospitalized for as long as 3 years. A rather profound anemia was present in most cases. Extensive liver damage resulting mainly from glycogen deficiency was not uncommon. Myocarditis was noted in about 25 per cent of the patients and clubbing of the fingers and toes was demonstrated in 22 patients. Rather severe polyarthritides was present in well over 50 per cent and a brain abscess led to the fatal termination of one case. Bronchial fistulas were common.

The various complications frequently of life-endangering severity could have been prevented by early diagnosis and adequate drainage. However, the extent of the empyema cavity frequently could not be determined even roentgenologically. Some large cavities were not diagnosed at all while others were believed to be much smaller than they actually were. Small cavities were occasionally overlooked especially when overlaid with aerated lung tissue or by an area of pleural thickening. The authors suggest the use of radiopaque substances in order to outline the residual cavities completely.

The types of operative therapy used were not discussed. However, it is quite probable that a limited thoracotomy with adequate drainage was performed. There were cures in 49 of 55 operative cases while 6 patients died either from the effects of the operation or within the immediate postoperative period. Five other patients who were not operated upon died from the combined effects of the underlying disease and several complications. ORVILLE F. GRIMES, M.D.

Primary Cancer of the Pleura. Roentgenologic and Endoscopic Symptomatology in 2 Cases (Sul carcinoma primitivo della pleura. Semelologia radiologica e endoscopica in due casi). GIUSEPPE TOJA and REMO MARIANI. *Atterno med.*, Tor. 1948, 39: 20.

Two cases of primary cancer of the pleura are reported by the authors. In one case that of a man 53 years of age the condition had existed 7 months and in the other case, that of a 50 year old woman it had existed 11 months prior to the admission to the hospital. The symptoms were pain in the chest, cough, dyspnea and asthenia.

Pleuroscopy and biopsy are the best diagnostic methods. They should supplement the x-ray studies, thoracentesis, and bronchoscopic and sputum examinations in cases in which the diagnosis is obscure. In early stages the primary cancer of the pleura can be easily mistaken for a simple pleurisy.

In both cases reported by the authors the diagnosis was confirmed by the autopsy.

The authors prefer the term "carcinoma" to "endothelioma" because there is no general agreement as to the embryologic origin of the pleura. The treatment in both cases consisted of repeated aspirations of fluid from the pleural cavity. X-ray treatment was not employed.

JOSEPH K. NERAT M.D.

HEART AND PERICARDIUM

Pneumopericardium. HERBERT WILLY MEYER.
J. Thorac. Surg. 9:3, 7-62.

Pneumopericardium, and particularly its complication by an infection is a rare condition. It would seem that the cases of traumatic origin offer a better prognosis than those in which the infection of the pericardium is part of a general sepsis.

The production of this condition may be varied but can be considered under three broad headings such as (1) trauma (2) perforation from neighboring organs and (3) spontaneous development of fluid, pus, and gas in the pericardium.

The physical signs include a disappearance of the cardiac area of dulness, fever and tachycardia are constant. Usually the pericardium is enlarged and effusion is present. Weird and varied auscultatory signs are described.

Röntgen studies are most valuable and paracentesis is required.

A case of pneumopericardium occurring in a 33 year old woman seen during military service is reported. She was admitted to days after being injured by a grenade fragment which penetrated the pericardium through the anterior chest wall. X-ray examination showed a typical pneumopericardium enclosing a foreign body. After suitable preparation over a period of 24 hours, an anterior pericardiectomy was performed, and the third to the sixth costal cartilages were resected. A portion of the sternum was resected away. The foreign body was removed and the wound was left open for drainage to be managed subsequently by daily irrigation. The patient did well for a time but subsequently died at another installation in uremic coma, on the nineteenth postoperative day.

MISCELLANEOUS

Latest Result (36 Years) of a Chondrectomy for Pulmonary Emphysema According to the Method of Freund (*Kunstato distans* (36 anni) di una condrectomia secondo Freund per enfisema polmonare). ANTONIO BOSCHI. *Boll. mens. Soc. piemontese chir.* 9:47, 7-65.

While examining a 70 year old patient who had consulted him for the relief of urinary disturbances (due to hypertrophy of the prostate gland) the author noticed a long linear scar on the right parasternal region of the patient's chest. On making fur-

ther inquiry he learned that the patient had undergone an operation for the relief of pulmonary emphysema 36 years before. His interest in this operation led the author to follow up the patient's past illness, review the literature and report the case.

The possibility of surgical cure of pulmonary emphysema was first expressed by W. A. Freund in 1859 on the basis of the hypothesis that emphysema was brought about by a morphological change in the thorax, the loss of elasticity of the costal cartilages being due to a certain fascicular derangement of the chondral tissue. The rigidity of the costal cartilage hinders the continuous movement of the thorax which accompanies the respiratory act and holds the thorax in a permanent position of inspiration. The lung subsequently becomes dilated.

At the turn of the century Freund restated his theory and in 1906 Hildebrand operated on the first case of pulmonary emphysema with favorable results.

Naturally discussion arose as to whether the rigid dilatation of the thorax in the position of inspiration was the causal factor of the emphysema, or whether the emphysema was due to a primary intrapulmonary lesion and the deformity of the thorax was a concomitant phenomenon.

Many clinical and anatomophysiological data were presented to support arguments in favor of both of these theories. Freund did not contend that his hypothesis of the origin of emphysema explained all cases of pulmonary emphysema. Numerous variations in surgical technique arose to improve the operation.

The author's patient revealed the following history 36 years earlier he had experienced difficulty in breathing, the difficulty being accompanied by periodic asthmatic attacks. He sought relief of his chest condition and entered the surgical service of the Clinical Institute of Surgical Pathology of the University of Torino. Here he was operated on according to the method proposed by Freund. Recovery was rapid and the patient's condition was greatly improved. After a year he had a recurrence of his difficulty in breathing, which this time was accompanied by cough, catarrh and asthma. This condition did not prevent him from serving in the Italian Army during World War I.

Physical examination 36 years after the operation showed the patient to be in good general condition. Inspection revealed a 30 cm. linear scar in the skin in the right parasternal region, the scar being loose and pliable. Expansion of the thorax was symmetrical but there was little motion of the chest on deep inspiration. The percussion note was resonant throughout. The lower border of the right lung was at the level of the ninth rib and that of the left lung was at the level of the tenth rib. Auscultation revealed medium and coarse rales throughout the chest. Roentgenograms showed the chest to be held in rigid inspiration, symmetrical on both sides with the lung fields clear and the shadows of the blood vessels and the bronchial tree accentuated. The dome of the diaphragm on the right side was at the ninth rib and

on the left side at the level of the tenth rib. The right ribs from the second to the fifth showed signs of irregular regeneration of bone at the site of the previous operation.

On looking up the operative record, the author found that his patient had been operated on by Mann on December 17, 1910, at which time a chondrectomy of the second to fifth right costal cartilages had been performed through a long right parasternal incision. Complete extirpation of the perichondrium in the case of each cartilage had been done and the ends of the denuded ribs were covered over by parts of the pectoralis major muscle. In the eyes of the surgeon such a disabling affection in the young patient of 35 years had seemed to justify the operation. Following the operation the patient's condition was markedly improved and when he reached the age of 39 in 1915 he served in the Italian army. At 70 years he showed typical emphysema, confirmed clinically and roentgenographically, but the condition inconvenienced the patient little and did not prevent him from working.

From a theoretical point of view it is interesting to note that the emphysema remained and that notwithstanding the destruction of the second to fifth right costal cartilages the thorax was symmetrical and was held in rigid in position with the dome of the diaphragm markedly depressed. In the long period of 36 years the anatomical condition became re-established and the fact that the intervention had had a favorable influence on the patient's condition was demonstrated by the clinical course of the case. The ends of the second to fifth ribs showed ossification at the costocartilaginous junctions and this contributed to the immobilization of the chest.

Whether pulmonary emphysema results from rigid deformity of the thorax as suggested by Freund or whether it is due to a primary pulmonary lesion as stated by Loeschle, the author concludes that surgical intervention according to the method of Freund is logical and should be carried out in certain selected cases which do not respond to medical treatment. He holds that surgical therapy is absolutely contraindicated in all cases complicated by chronic pulmonary infections and circulatory disorders in spite of the opinion of other authorities.

BLACKWELL STARRHAM M D

Traumatic Diaphragmatic Hernia. STACY HUGHES, LARRY H. KAY, P. H. MEYER, JR., T. R. HURSON and JULIAN JOHNSON. *J. Thorac. Surg.* 1918, 17, 99.

Between January 1914 and April 1916 25 traumatic diaphragmatic hernia were operated upon by the Chest Surgical Section of the Kennedy General

Hospital at Memphis, Tennessee. Sixteen of these were in battle casualties, the remainder being unrelated to battle. In 17 cases the hernias were due to penetrating wounds and in 11 cases to contusions.

The location and extent of the diaphragmatic defect could not uniformly be correlated to classic areas of anatomic predilection, the wounding agent or to the severity of the original trauma. The herniation occurred immediately after the original injury in most instances, but good evidence is adduced that herniation occurred only as the result of added strain as long as a year after the injury. The dome of the left diaphragm was the site most frequently involved and accounted for 12 cases. The right side was involved five times and the remaining cases occupied various sites on the left side.

Not all cases were diagnosable preoperatively. Hernias were discovered as the result of exploratory thoracotomy in 8 cases. In the cases with hollow viscera a preoperative diagnosis is relatively simple roentgenographically, however. In only 2 cases was a true sac found. Adhesions, however, were always present. One hernia had extended into the pericardium.

The patients were operated upon trans thoracically with adequate control of the operative field. In one instance resection of a segment of gangrenous colon was carried out. The ends were brought out as a colostomy through a left rectus incision. Also in one instance a cystic kidney was removed as a viscus contained within the hernia.

The diaphragm was repaired by two layers of interrupted silk sutures. If the muscle had been separated from the chest wall it was reapproximated by sutures anchored through the chest wall buttressed by an intrapleural repair as well. The phrenic nerve was cruised as a routine in the latter part of the series after a recurrence of the hernia occurred within 24 hours. This accident was presumed to be due to strenuous efforts directed at clearing the airway. It was believed that the phrenic paralysis did not interfere with diaphragmatic healing. A ventral successful repair was obtained in all instances.

The complications included the early recurrence mentioned, transient pleural effusion, three times, transient pneumothorax once and an empyema once. No deaths are recorded. Obstructive symptoms demanded emergency operation five times.

Emphasis is placed on the possibility of late development of herniation as the result of some added strain even though the original trauma may have been slight.

The article is amply illustrated.

HIRSH T. LANE, M D

SURGERY OF THE ABDOMEN

ABDOMINAL WALL AND PERITONEUM

Mesenteric Cysts. MILLER PAUL. *Arch. Surg.* 1948, 35: 308.

The case of a mesenteric cyst which caused repeated attacks of acute intestinal obstruction from its recurrent impaction in the pelvis is reported. Most mesenteric cysts are not diagnosed before operation because their occurrence is not borne in mind. Diagnosis may be difficult because of the small size or because of the large size of the cyst. In most cases, however, there is usually a well-defined central intra-abdominal cyst with mobility greater in the transverse than in the longitudinal direction. Complications arising from intestinal obstruction, intra-cystic hemorrhage or infection and from rupture into the peritoneal cavity may be encountered.

Enucleation of the cyst would be the ideal treatment but it is not always practicable. Care must be taken to avoid injury to the mesenteric vessels during the dissection of the cyst wall. Manipulation of the cyst has been performed in cases in which dissection was considered too hazardous, following which the cyst has remained empty. A similar result has occasionally followed simple aspiration. In cases with involvement of the bowel by a complication, resection of the bowel together with the cyst has sometimes been done.

In the reported case, enucleation was successful. Histological examination of the cyst wall showed it to be a replica of small intestinal wall, lending support to the theory that these cysts originate from sequestration of a portion of the wall of the small intestine. The view that the fluid content of these cysts is often an accidental circumstance determined by the opening up of lymph or chyle vessels into the lumen of the cyst is favored by the findings in this case.

JOHN L. LINDEQUIST, M.D.

GASTROINTESTINAL TRACT

Gastroduodenal Ulcer a Spastic Disease. I. BOKERMA. *Ann. Surg.* 1948, 74: 3.

This intriguing report is the result of observations during the course of extensive experiments in which a team of 21 investigators collaborated, most of whom were connected with Dutch universities. The German occupation of Holland, during which the entire population of 9,000,000 people were medically *de facto* experimental subjects, furnished a great deal of material which it is believed may throw some light on the theory of ulcer formation.

In Holland, as in the United States, an increased number of ulcers occurred immediately after the outbreak of war. Factors contributing to this situation included psychic factors such as fear, sorrow and rage and later important changes in the diet. For many years the daily intake consisted of a total of

about 1600 calories with a relative diminution in consumption of protein and fat, and an increase in carbohydrates. Potatoes, a food high in cellulose, were eaten in much larger quantities than normal. These changes produced an increased peristalsis throughout the gastrointestinal tract of nearly the whole population with the result that many persons even suffered from nonbacterial diarrhea throughout the entire period of the occupation.

The increased incidence of volvulus, especially of the sigmoid strangulated hernia, and anal fissures was observed in great numbers of individuals, while there was a diminution in the incidence of acute appendicitis. This observation indicates that increased peristalsis and spasticity of the gastrointestinal tract lead to a higher incidence of such lesions at the same time preventing the stagnation of secretions in the appendix.

Pyloric hypertrophy in adults in Holland was frequently observed, an indication of increased frequency of a spastic condition of the stomach. Roentgenologists demonstrated many cases in which the entire antrum of the stomach was rigid. Laparotomy revealed either cancer nor ulcer but hypertrophy of the pylorus. Such direct observations of increase of frequency in spasm in the stomach sustain the neurogenic theory of ulcer of Von Bergmann. Interestingly enough, acidity of the gastric secretion decreased rather than increased during the occupation. Hence these observations do not support the theory of high acidity as the prime cause of gastroduodenal ulcer.

These considerations, plus others presented by the author, caused him and his group to examine the rationale for hundreds of resections performed daily for the treatment of gastroduodenal ulcer. The experiences during the occupation led them to conclude that diminishing the gastric acidity cannot be the cause of the success of gastric resection. In the author's opinion, the chief effect of resection seems to be the removal of that part of the gastroduodenum most susceptible to the spasm assumed to be the direct cause of the ulcers.

The present study while not affecting therapy has, in fact, led the author to the conviction that gastroduodenal ulcer is a spastic disease.

HAROLD LAUFMAN, M.D.

Superficial Spreading Carcinoma of the Stomach. ROSE GOLDEN and ARTHUR PURDY STOUT. *Am. J. Roentg.* 1948, 59: 157.

Carcinoma of the stomach, in order to be detected by roentgen examination, must produce alterations in the form or movement of the stomach wall. The demonstrability depends upon the location in the stomach and the gross growth characteristics of the neoplasm. The large majority of gastric carcinomas (95 per cent) occur in the antrum or media of the stomach where demonstration is very probable.

Malignant tumors have two basic growth characteristics (1) the mass-producing quality and (2) the invading or infiltrating quality. Upon these physical growth characteristics Stout has based the following classification of carcinomas of the stomach:

1. Fungating grows into lumen and produces a mass (occurred in 25 per cent of 200 cases)
2. Spreading grows along wall and produces no mass.
 - a. Superficial spreads in the mucosa and submucosa (occurred in 14 per cent of 200 cases)
 - (1) Ulcerating about 80 per cent
 - (2) Nonulcerating about 20 per cent.
 - b. Limitis plastica type spreads in the submucosa muscle coat and subserosa (occurred in only 2.5 per cent of 200 cases)
3. Penetrating grows through the wall to the serosa (occurred in 26 per cent of 200 cases)
4. Unclassifiable advanced growths found in 32.5 per cent of 200 cases.

The discussion is concerned with the superficial spreading type and its differential diagnosis. Superficial spreading carcinoma begins in and grows along the mucosa, replaces the mucous membrane and usually obliterates the mucosal folds. It usually penetrates the muscularis mucosae into the submucosa and may rarely penetrate to the serosa, but it does not destroy or replace the muscle. In contrast to the penetrating type, gastritis is invariably associated with carcinoma of the stomach.

In the past decade, 31 superficial spreading carcinomas of the stomach have been discovered by the Department of Surgical Pathology of the Presbyterian Hospital, New York. The average length of time between the onset of symptoms referable to the stomach and hospitalization was almost 2 years, the longest was 10 years and the shortest 1 month. One case was asymptomatic.

Sixty-seven per cent of the patients were men and 33 per cent were women. Their ages varied from 34 to 80 years, with the largest number (15) between 50 and 60 years.

One stomach contained 2 superficial spreading cancers. They varied in size from 1 sq. cm. to 180 sq. cm. In 2 cases mixed types of carcinomas were present. Two other cases showed multiple foci of superficial spreading cancer with uninvolved mucous membrane between them.

Metastases to the regional lymph nodes were present in only 15 of the 31 cases. The superficial cancer developed in the lower half of the stomach in 30 of the 31 cases. Cancer developed around an open peptic ulcer in 12 cases, in 3 of which secondary ulceration in the cancer occurred. In 2 cases cancer developed in the mucous membrane over the scar of a healed peptic ulcer. The carcinoma itself ulcerated in 14 cases, in addition to the 3 ulcerating cancers associated with open peptic ulcers already mentioned. In 4 cases superficial spreading cancer was present without ulcer.

An open ulcer was present therefore in 26 or 80 per cent of 31 cases. Ca trephery was performed in

11 cases and in 9 of these evidence was found which was consistent with or suggestive of cancer although in some cases multiple examinations were necessary. In 2 cases no evidence of cancer was apparent. There is little doubt that cancer developed during the period of examination in 2 cases.

Twenty nine of the 31 patients had roentgen examinations at Presbyterian Hospital of which 24 had either cancer or peptic ulcer with cancer. In 20 of these the ulcer was demonstrated by roentgenograms. Elongated spasm of the antrum associated with gastritis was found in 6 of the 20 cases, and a localized incisure at the level of the diseased area in 3 cases.

The difficulty in the diagnosis of superficial spreading carcinoma of the stomach lies mainly in three problems. These are the detection of cancer developing around an open peptic ulcer, the detection of cancer developing in association with spasm of the antrum and the possible effect of cancer growing in the mucosa alone or in the mucosa and submucosa, on peristaltic movements and flexibility of the wall. Roentgenograms taken *en face* may show that mucosal folds run into a peptic ulcer crater but stop at the edge of cancer. Under treatment a peptic ulcer should diminish in all directions but a cancerous crater diminishes in depth but little or not at all in transverse diameter.

Cancer causes muscular spasm and when the spasm increases either in degree or length during observation, carcinoma should be suspected.

It seems advisable to assume that carcinoma is probably present if dampening or obliteration of the peristaltic impression occurs over a localized area particularly if small irregularities of the margin or other suggestive signs are present.

This article contains some excellent photographs of roentgenograms which exemplify the subject material.

LESLIE D. BLOOMENTAL, M.D.

Vagus Nerve Resections. WALTMAN, WALTERS, HAROLD A. NEUBERG, WILLIAM F. BRADLEY, JOHN T. SWALL, and JAMES W. WILSON. *J. Am. M. Ass.*, 1948, 136, 742.

The present report is confined to a summary of the results of resections of the vagus nerve in the treatment of peptic ulcer, both favorable and unfavorable. In the authors' cases, which now total 50, and in the cases of their colleagues which now total 68. In the authors' cases resection of the vagus nerve had been performed in 34 patients with duodenal ulcer in 7 with gastric ulcer and in 9 patients with gastric ulcer. The patients who were selected to undergo resection of the vagus nerve were chosen from that group of approximately 12 per cent of all patients with duodenal ulcer (at the Mayo Clinic) in whom an operation of some type was thought to be necessary, since nonsurgical methods had failed. In only 19 of the authors' series of 50 cases was it thought advisable to do a vagus nerve resection without some other simultaneous operation on the stomach such as a drainage operation to prevent postoperative gastric stasis or excision of a gastric ulcerating

lesion in their colleagues series vagotomy was done in 3 of 68 cases without other procedure on the stomach.

A complete vagus nerve resection relieves the pain of ulcer and there is a marked reduction of gastric acidity to an achlorhydric state in more than 50 per cent of cases. These results are secured at the expense of tonicity of the stomach, dilatation of the stomach occurs, and may produce troublesome symptoms such as frequent belching of foul gas, a feeling of epigastric fullness and occasionally nausea, vomiting and diarrhea. In the authors' experience, relatively few of the patients with duodenal ulcer who are operated on at Mayo Clinic have nonobstructing ulcers.

In only 6 of the 34 patients with duodenal ulcers who were operated on by the authors had vagotomy been done without other simultaneous gastric operations. Six had complete relief of symptoms, some up to a year after operation. Despite this, roentgenologic examination on diastol showed a duodenal ulcer without crater in 4 patients, 2 of whom gave a positive reaction to the insulin test. Three of the 10 patients had no distress from the ulcer but did have fullness and bloating, and 1 of the 3 was having diarrhea 6 months postoperatively. One of the 10 patients died one hour after operation of coronary insufficiency.

Sixteen of 22 patients who underwent vagotomy associated with gastroenterostomy had good results despite the fact that 7 had some fullness after meals in the early postoperative period, and 1 of the 7 had a physiologic obstruction for 20 days which necessitated jejunojunctionostomy. Four patients had mild symptoms of diarrhea with bowels moving loosely two to four times a day. Two patients had early retention of gastric contents and later had bad results.

Two patients had other gastric operations—one, a partial resection, the other excision of the ulcer and pyloroplasty. Both patients obtained relief of the distress from ulcer; the results of the insulin test were negative and there was achlorhydria.

There were 7 cases of gastrojejunal or postoperative gastroduodenal ulceration. These patients gave histories of intractable pain of long duration. In 4 of the 7 results were excellent, with relief of pain and with no complaints of fullness, bloating, nausea, or diarrhea; the other 3 patients had what might be considered satisfactory results.

It was considered advisable to perform vagus nerve resection in a small series of patients with gastric ulcers of various sizes, in order to determine the results of the operation and to compare them with the results in patients who had undergone partial gastrectomy for ulcer. Nine patients were chosen for the procedure. The 9 patients with gastric ulcer obtained relief from pain and reduction of gastric acidity but 3 had prolonged disturbances of motility. One ulcer failed to heal and one ulcer recurred despite apparent complete section of the vagus nerves, as demonstrated by clinical and laboratory tests including the insulin test.

The 63 patients on whom operation was performed by colleagues of the authors at the Clinic included 37 with duodenal ulcer, 30 with gastrojejunal ulcer and 1 patient only with gastric ulcer. In 8 patients with duodenal ulcer vagotomy only was performed; in 5 of these, the operation was done transabdominally and in 3 abdominally. Four of the 5 patients who underwent vagotomy by the transabdominal approach had good results, although 2 had some trouble immediately after operation. One patient had early retention with belching and fullness; this patient had a reduction in gastric acidity but no insulin test was done. Eight months after operation he had no distress from ulcer but he complained of gas and occasional episodes of diarrhea. One of the 3 patients who underwent abdominal vagotomy was well at dismissal and had a reduction of gastric acidity. Another patient had retention early after operation with intermittent periods of vomiting and diarrhea 3 months postoperatively. The third patient died suddenly on the fourth postoperative day and, although autopsy was not performed, death was thought to be due to an embolus.

Twenty-five patients with duodenal ulcer underwent vagotomy and gastroenterostomy. Twenty-four of these had relief of symptoms of ulcer. However, 6 patients had disturbances of motility characterized by epigastric fullness, nausea, or diarrhea. One patient with marked postoperative gastric retention and hypoproteinemia died on the fourteenth postoperative day. At necropsy an unexpected perforated duodenal ulcer with subdiaphragmatic abscess was found. Four patients underwent pyloroplasty in addition to vagotomy. All of these obtained relief of distress from ulcer. Only 2 had disturbances of motility of any consequence.

There were 30 cases of gastrojejunal ulcer in which vagotomy was done. In 3 of these the operation was performed too recently to permit of evaluation. Of the remaining 27 cases in 15 the operations were done transabdominally and in 12 abdominally. Nine of the 15 patients had good results from transabdominal vagotomy with absence of all symptoms of ulcer. Three patients had unsatisfactory results with recurrence of the symptoms of ulcer.

In 7 patients the existing anastomosis was not disturbed, the abdominal approach being used. 4 of these had had previous gastroenterostomy and 3 gastric resection. Three had obtained good results clinically; 3 still complained of minor degrees of fullness and diarrhea several months after operation, and the remaining patient noticed gas and dizziness when hungry which was relieved by frequent small meals.

One patient underwent disconnection of the enteric stoma as well as vagotomy. He had no drop in gastric acidity and the insulin test gave positive results. He suffered from retention and vomiting for a month and was still belching foul gas and vomiting occasionally 4 months later.

One patient underwent disconnection of the enteric stoma and pyloroplasty with good results. One pa-

tient had the gastroenteric stoma disconnected and a gastroduodenostomy was done. He had occasional ulcer distress and fullness but he was in good health otherwise. Two patients with gastrojejunocolic fistula had good early results after disconnection of the enteric stoma, closure of the fistula, and re-establishment of the enteric stoma, in addition to vagotomy. One patient died at home 3½ months after operation from a coronary occlusion (as reported by his home doctor).

Only 1 patient with gastric ulcer which was located in the pyloric ring was studied by the authors' colleagues. The ulcer was excised and pyloroplasty was done simultaneously. The patient obtained early relief of symptoms and a reduction in acidity. No insulin test or postoperative roentgenogram was made.

Measured Radical Gastrectomy A. HENLEY VISCICK *Lancet* Lond., 1948, 1: 505-557

To discover the limitations and the advantages of a Polya type of gastrectomy a consecutive series of 500 cases has been followed up by the author at regular 6 month intervals since operation. This series included all patients operated upon by the author in the period from 1936 to 1947 except those given emergency treatment.

The indication for operation in most patients was severe and persistent pain unrelieved by medical treatment. The distribution of the ulcers was as follows:

Type of Ulcer	Male	Female	Total
Duodenal	321	35	357
Gastric	47	21	68
Combined	38	7	45
Secondary	32	3	35
	439	66	505

The terms gastrectomy, partial gastrectomy, and subtotal gastrectomy have no precise anatomical significance. Most surgeons remove either 'half' to two-thirds or two-thirds to three-quarters of the stomach, but the author feels strongly that the size of the ventriculus remaining is more important than the portion of the stomach removed. Thus, instead of making what is inevitably a vague guess at the proportion of stomach removed, a concentrated effort is made to measure the exact size of the part left *in situ*. The line of section of the stomach is made so as to leave a small devascularized remnant 1½ inches along the lesser curvature and 3 inches along the greater curvature (Fig. 1).

The measured radical gastrectomy differs from a conventional three-quarters gastrectomy in three respects: the area of stomach which remains can be measured and controlled with accuracy; the gastric remnant is extensively devascularized; and in 98 per cent of the cases permanent achlorhydria results. The essential point of technique is division of all but one of the vasa brevia and all branches of the left gastroepiploic artery (Fig. 2).

Fig. 1 (Visick) Levels of section in different types of gastrectomy in relation to the blood supply. A: Measured radical gastrectomy. B: two-thirds to three-quarters gastrectomy. C: half to two-thirds gastrectomy.

Fig. 2 Effect of division of the blood vessels supplying stomach. a, in two-thirds to three-quarters gastrectomy point A remains anchored against the hilum of the spleen. b, in measured radical gastrectomy after division of the vasa brevia, point A falls away from the spleen and presents in the wound. Note change in the shape of the stomach after division of the blood vessels.

The operative mortality for the last 430 operations was only 3.7 per cent. Of the 430 patients examined from 6 months to 12 years after operation, 95 per cent showed satisfactory results. The year-by-year continuous follow-up indicates that results improve with time: provided the follow-up is intensive. Every patient is seen at monthly intervals for the first 6 months, after which he is transferred to the gastric follow-up clinic, where he is seen by appointment every 6 months.

No case of macrocytic anemia was noted despite the extensive radical resection performed. No ulcer was found to recur later than 28 months after operation. In dealing with recurrent ulcer it should be discussed in precise terms—the exact extent of resection, the time that has elapsed since operation, and the type of ulcer for which the operation was planned.

EDWARD F. LEWISON, M.D.

Peptic Ulcer in the Aged. HENRY A. RAFFERTY, MICHAEL WEINGARTEN, and CHARLES I. KRIEGER. *J. Am. Med. Ass.*, 1948, 136: 759.

In a series of 1,800 successive patients admitted to the hospital for peptic ulcer, 81, or 4.5 per cent, had no symptoms referable to the ulcer prior to reaching the age of 60. Fifty-eight per cent of the 81 patients had complications of ulcer on admission. Hemorrhage was the chief complaint in 38 per cent of the

cases The mortality from hemorrhage in this series was 10.7 per cent. No case of bleeding was treated surgically. Liberal use of slowly administered infusions and transfusions is advocated, when necessary in the treatment of hemorrhage due to ulcer in the aged. Hypertension is not a contraindication to these measures.

Perforation was the initial evidence of ulcer in 13.8 per cent of the cases and the mortality as a result of this complication is high. Pyloric obstruction due to ulcer in the aged often yields to medical treatment. Surgical treatment is imperative in those cases in which the obstruction is refractory to medical therapy.

Complicating diseases play an important role in the prognosis of ulcer in elderly patients.

SAMUEL KAHN, M.D.

End Results in the Treatment of Peptic Ulcer by Posterior Gastroenterostomy WILLIAM A. COOPER, *Surgery* 94:6, 23, 4, 5.

The end-results in the treatment of peptic ulcer by posterior gastroenterostomy have probably never been accurately judged in the past. The purpose of this report was not to compare the results of gastroenterostomy and gastric resection, but to give as complete and clear a picture as possible of what one can expect from the older procedure gastroenterostomy. Unless vagotomy clearly proves to be the panacea that all those interested in this field have long looked for, there is reason to believe that the evaluation of gastric operations will be further beclouded. This is particularly true if vagotomy is to be used simultaneously with gastroenterostomy or resection.

The author utilizes his own method of statistical analysis involving the plotting of a failure curve. An analysis is made of poor results from the standpoint of pathology, clinical symptoms, correlation of symptoms before and after gastroenterostomy, diagnostic value of roentgenology and gastroscopy, factors influencing end results, results in age groups, results in nationality groups, results in clinical groups, and results in gastric ulcers. Furthermore an analysis is made of the results of treatment in fall res. This is done from the standpoint of results of conservative treatment and of operative treatment.

It became apparent from the failure curve plotted by the author that one can expect about 25 per cent of patients after gastroenterostomy to have recurrent symptoms, usually within 5 years after operation and that about one-quarter of these will eventually become well without further surgery. From the pathology found in the patients to whom the operation failed it is clear that if the recurrent symptoms are persistent they will in all probability be due to a marginal ulcer rather than to reactivation or persistence of the primary ulcer. Since most of the primary ulcers in this series healed after gastroenterostomy it would appear that the procedure was a very effective method of dealing

with the primary lesion. It would seem that much of the talk one hears about reactivation of duodenal lesions after gastroenterostomy is fallacious. Indeed, one is led to the general conclusion that if the gastroenterostomy functions, the primary duodenal ulcer will heal whether it be an obstructing ulcer, a penetrating ulcer or a bleeding ulcer. The only exception in this series was one in which the stoma functioned poorly. The only other exceptions (not in this series) occurred late, when involvement of the stoma by marginal ulcer led to poor function of the stoma and consequent reactivation of the original duodenal ulcer.

Effective as gastroenterostomy may be for the treatment of primary ulcer it is perfectly clear that it often fails to prevent the formation of new ulcers, thus it fails to interrupt the ulcer diathesis. The impression exists that gastric resection is more effective than gastroenterostomy in this regard, but it is well known that resection also fails in certain cases. From the analysis of the secondary operations done it is apparent that certain patients have such a marked ulcer diathesis that they do poorly with both gastroenterostomy and resection.

It is probably accurate to state that most of the surgeons in this country have come to believe that gastroenterostomy is an inadequate and poor operation. In the light of experience in the present series this view is open to some question. Until vagotomy has been evaluated the alternative to gastroenterostomy is usually gastric resection. Had resection been attempted on all patients, the author believes the mortality would have been high if not formidable, particularly in the group selected for gastroenterostomy since 1939 for among them were the poor risks.

A comparative evaluation of gastroenterostomy will have to await the completion of similar studies of end-results in gastric resection but the low mortality and generally favorable outlook reflected in the failure curves strongly support the view that gastroenterostomy is a useful and often curative procedure which has a definite place in the repertory of gastric surgery. It may be that the passage of time and accumulation of experience will show that gastroenterostomy supplemented by vagotomy in cases in which it fails, will give the lowest mortality and the highest incidence of cures.

HAROLD LAUTMAN, M.D.

Late Results following Perforated Peptic Ulcer S. W. MOORE and ROBERT HENDERSON, *Surgery* 94:8, 7, 442.

The authors' study was undertaken to determine the end results in patients with perforated peptic ulcers operated upon in Bellevue Hospital, Second Surgical Division (Cornell). The cases of 101 patients who were treated on this service from 1928 to 1945 for perforated peptic ulcer are reviewed and the results of follow-up studies are presented.

From a statistical analysis based on a careful breakdown of the various factors involved the authors have drawn the following conclusions:

Patients with perforated ulcers should be operated upon promptly the perforation should be closed by simple suture when simple suture causes obstruction it should be combined with gastroenterostomy. No drainage is employed in the abdominal wound. Patients who have persistent symptoms or who have an active ulcer (or both) at 6 months after operation, and while on adequate medical treatment should have additional operative treatment.

Secondary operations were carried out in 17 cases for reoperation hemorrhage obstruction or intractable pain. It is quite clear that although the immediate results of surgery for perforated ulcer are good the late results as determined by follow-up studies are poor. The answer to this problem does not lie apparently in altering the initial operative technique. An analysis of cases showed that simple closure is still the procedure of choice except when the closure results in obstruction.

HAROLD LAUFMAN, M.D.

Duodenal Ulcer. MAURICE FELDMAN. *J Am M Ass* 1948 136 736

A comparative statistical study of duodenal ulceration in the civilian population was made of two 5 year periods: the prewar period (from 1937 to 1941) and the period during the war (from 1942 to 1946) to determine the effect of the war on duodenal ulceration.

There was a rising trend in the incidence of duodenal ulcer during and immediately after the war. This amounted to about 4 per cent. The comparison of the age and sex incidence in duodenal ulcers between the prewar and postwar periods showed no significant statistical change. There was a slight increase in the incidence of cases of less than one year's duration in the second 5 year period. There was a slight increase in the number of ulcer niches observed by roentgenography in the wartime cases as well as a slight increase in the number of niches occurring in females in the war group.

During the war period there was a higher incidence of first recurrences and an increase in the incidence of acute ulcers. In many instances the severity of every form seemed to be more pronounced during the war period because of the increased number of acute ulcers.

The complication obstructive and hemorrhage were not statistically different in the two groups of cases. There was a greater incidence of hematemesis in females during the war period.

SAMUEL FANN, M.D.

Effect of Intestinal Gases upon Balloons of Intestinal Decompression Tubes. MYRTLE O. CANTOR, IRENE R. PHILLIPS and FORREST H. LUND. *Am J S* 1948 75 445

Experiments were conducted to study the permeability of intestinal gases through the wall of balloons of the various intestinal tubes. It was found that all balloons of intestinal decompression tubes are permeable to intestinal gases. Carbon dioxide and

hydrogen sulfide are the gases most likely to diffuse into the balloons of intestinal decompression tubes because of their high degree of diffusibility and because of the markedly higher concentration of these gases within the bowel as compared with their concentration within the balloon.

The authors describe their method of preventing gases from accumulating in the balloons of intestinal tubes which consists in applying the tie to the balloon in such a fashion that the mercury remains trapped within the balloon but air can enter and leave. In addition they urge that all balloons be made of neoprene-G. This type of rubber is only 10 per cent as permeable to carbon dioxide as is latex rubber. By these two changes the authors claim to prevent any accumulation of intestinal gases within the balloon.

Prolonged soaking of the balloon in intestinal secretions does not increase its permeability; neither does the presence of mercury within the balloon for long periods of time increase its permeability.

HAROLD LAUFMAN, M.D.

Clearing Intestinal Tuberculosis and Regional Enteritis. J. R. LINDERG. *Ann Chir Gyn Scand* 1947 36 219.

This study is concerned with the relationship between so-called hyperplastic or stenosing intestinal tuberculosis and regional enteritis. The cases discussed were observed between 1908 and 1937 at Surgical Clinic I, Helsinki, and included 39 patients treated by resection, 15 treated by short-circuiting and 1 patient treated by enteroplasty. The last 16 cases were not confirmed by microscopic section and are excluded. Twenty-six cases were studied by careful microscopy.

Tuberculosis was found in only 10 (65%) of this group of cases. In 5 cases a nontuberculous enteritis was found and in 2 cases respectively a carcinoma of the rectum and a sarcoma of the ileum. During the last decade no resections for intestinal tuberculosis have been performed.

Intestinal tuberculosis of the hyperplastic type is very rare (6%). The stenosing type of nontuberculous enteritis was found to be even more rare by the author although other authorities have described it as more common than the tuberculous type.

In most of the cases of hyperplastic intestinal tuberculosis the lesion appeared to be an isolated primary form of the disease as pulmonary tuberculosis was rarely diagnosed. The intestinal lesion was in the terminal ileum and cecum in 1 of 20 cases. The regional lymph nodes were also involved. When the cecum was involved the specimen usually conveyed the impression of a tumor. Strictures and ulcers were noted in various cases. Tubercles and increased connective tissue were typical findings. Ulcers in the ileum tended to penetrate through to the serosa while in the cecum they were usually superficial.

In the cases of nontuberculous enteritis a marked diffuse thickening was present as a result of deep

plasma cell and lymphocytic infiltration. The lesions were sharply delimited at the ileocecal valve. The peritoneum was thickened and bands were frequently present which made the bowel very tortuous. Cell conglomeration suggestive of tuberculosis and giant cells of the Langhans type were never observed in these cases. Small ulcers located at the mesenteric attachment were typical as were fistula formations and scars.

The pathogenesis of intestinal tuberculosis probably occurs through the lumen and in many cases a pulmonary focus was found as the primary lesion. The pathogenesis of regional ileitis appears to initiate from within the submucosa of the bowel.

Twenty-three patients with intestinal tuberculosis were treated by surgical intervention and in 16 an ileocecal resection was performed. The resection mortality was 45 per cent. Of the 11 patients discharged 4 died many years and the remaining 7 died from 2 to 5 months of tuberculosis.

The patients with nontuberculous enteritis were also treated by resection, but no mortality resulted.

E. VERT D. BLOOMENTHAL, M.D.

The Sigmoid as a Source of Right-Sided Symptoms.
ALB. T. S. LYONS. *Ann. Surg.* 1918, 17, 395.

The author cites 18 cases to demonstrate the frequency with which the sigmoid may be the cause of right-sided abdominal symptoms. The commonest preoperative diagnosis in these instances is acute appendicitis.

In the author's experience the principal causes for right-sided symptomatology resulting from sigmoid lesions are diverticulitis and carcinoma. Reasons for this clinical picture are the sigmoid lies on the right side of the abdomen as a result of its mobility, or anatomical variations in its course perforation of the right wall of the sigmoid, with spillage of exudate into the right iliac fossa, extension of a perisigmoidal abscess to the right, adherence of right-sided structures to the sigmoidal lesion, marked distention of the cecum and situs in crura.

The suggestion is made that inspection of the sigmoid should be included with the exploration of the abdomen before removal of the appendix when at operation insufficient cause for the clinical findings is discovered in the right iliac fossa.

HAROLD LATHROP, M.D.

Hirschsprung's Disease. J. A. JENSEN. *Austral. J. Zool. J. Surg.* 1918, 7, 85.

Three cases of Hirschsprung's disease are described with a view to adding information to the subject. In 2 cases of abdominal distension in which spinal anesthesia did not effectively evacuate the colon, partial bilateral sphincterectomy caused daily adequate bowel motions with the aid of ingested paraffin. In one of these the whole of the colon also was resected. The third patient was benefited but little after bilateral sphincterectomy and eventually died of massive collapse of the lung following resection of the colon and left lumbar sympathectomy.

The operative technique for partial bilateral sphincterectomy is described and illustrated. A wedge of the internal anal sphincter is removed bilaterally. No sutures are placed.

The nervous physiology of the colon and external anal sphincter is discussed. The rationale of lumbar sympathectomy is based on the belief that the sympathetic nerves are motor to the sphincter and inhibitory to the rectum and colon and the parasympathetic nerves are inhibitory to the sphincter and motor to the rectum and colon. A mass of contrary evidence is cited particularly the facts that low spinal anesthesia abolishes sphincter tone and that presacral neurectomy does not.

The nervous control of the colon in Hirschsprung's disease is discussed. Most authors postulate an inhibitory action on the colon by the thoracolumbar sympathetic outflow. A failure of development of the defecation reflex might result in hypertrophy and spasm of the internal anal sphincter and a diminution of sensory activity of the colon.

Following full radiological investigation, the induction of high spinal anesthesia is the first line of attack. It may prove effective therapeutically and also may indicate sympathectomy. Next bilateral partial sphincterectomy should be performed. All patients with gross dilatation of the pelvic colon should have this loop resected by a Mikulicz-Paul type of operation but only after thoracic development has been improved. If recovery is not then complete right lumbar sympathectomy may be indicated.

ERNEST D. BLOOMENTHAL, M.D.

Cancer of the Rectum. E. J. BOGGS. *Ind. J. Surg.* 1917, 6.

One hundred and thirteen cases admitted in a 55 year period to the Tata Memorial Hospital in Bombay, India, are discussed. The ages of the patients varied from 17 to 85, the largest number of patients being in the fifth and sixth decades. Males predominated at a rate of 3 to 1.

Cancer rising in a polyp occurred only once and then in a European woman. It is the author's opinion that rectal polyposis is infrequent in India.

Diagnosis was made by means of digital examination, barium enema proctoscopy and biopsy. The neglect of digital examination is cited as the chief cause for delay in admitting the patient to the hospital for surgery.

The histological types encountered were adenocarcinoma in 43, squamous carcinoma in 33, adenoma malignum in 6, colloid carcinoma in 4, and myosarcoma in 1. There was a much higher incidence of squamous carcinoma here, than in Europe and America (Bacon, 6% and Gabriel, 35%).

The prognosis was adequately forecast by the Dukes classification as group A (within the rectal wall) yielded 84 per cent of cures, group B (penetration into the perirectal tissues) yielded 62 per cent of cures, and group C yielded 3 per cent of cures. The histological character of the lesion indicated the fate of the patient to a lesser extent but grades 3

and 4 lesions and colloid cancers were apt to be disseminated early and widely.

The Lahey two-stage operation was used early but was superseded in the latter part of the group by the Miles one-stage operation because of its greater acceptability to the patient, less chance for complications and the lack of adhesions. The two-stage operation is now used only in debilitated patients with obstruction, inflammation or both.

Radium and x rays were used palliatively when the patient was unfit for surgery or the lesion inoperable. Results were better in squamous cell carcinoma than in adenocarcinoma.

Preoperative preparation consisted of tests for blood counts, blood protein, nonprotein nitrogen, sugar estimations, urinalysis, cardiac efficiency tests with correction of the deficiencies. Purgation was avoided and two enemas given the day before surgery cleared the bowel adequately. When incomplete obstruction was present daily enemas and small doses of magnesium sulfate were used. General anesthesia was used in preference to spinal anesthesia in most cases because of its greater duration.

Thirty radical resections were performed with mortality in 3 cases. One death occurred among 10 patients subjected to the Miles operation and 2 deaths occurred among 9 patients subjected to the two-stage Lahey operation. Eight perineal excisions (used when the condition of the patient was not suitable for radical resection), 1 perineoabdominal operation, 1 Hartman operation and 1 Babcock operation resulted in no mortalities. Twelve of the 30 patients are dead, none could not be traced. Seventeen are alive from 1 to 5 years after operation.

The author prefers the one-stage abdomino-perineal operation but also used Miles technique except that he used a left incision instead of a right and brought the colostomy out through the incision.

Postoperative treatment entails necessary infusions and an indwelling catheter for the first 48 hours. The perineal pack is removed after from 24 to 48 hours postoperatively. Complications were few, the most frequent urinary sepsis, occurring 9 times.

The author is intrigued by Babcock's operation for preservation of the sphincter but fears that it may prevent the most radical extirpation of the cancer.

EXTENT D. BLOOMER, M.D.
Resection of the Rectum with Preservation of the Anal Sphincter. WILLIAM F. NICKEL, J.R., and ARTHUR I. CHENOWETH. Surgery 1948 33 450.

The highly controversial question of resection of the rectum for rectal cancer, with preservation of the anal sphincters, is reviewed by the authors and 68 cases are analyzed. Sixty-one patients were operated upon 5 years or more before publication of the present article. Of these 62 per cent survived for a period of 3 years, 40 per cent survived for a period of 5 years and 26 per cent survived for a period of 10 years.

The authors state that it would be futile to go to great lengths to preserve the anal sphincters if after their preservation, they failed to function. In analyzing the functional results of this group of patients the authors were very strict in making their assessment in a sincere desire to judge the efficacy of the technique. Excluding the cases which could not be followed up and those which resulted in death, there were 34 cases suitable for evaluation from the standpoint of the reconstructed anal outlet.

Results were evaluated as follows: (1) perfect in dictating normal control regardless of consistency of stools, no staining and the presence of a sphincter which on examination contracts normally; (2) good indicating control of bowels with no soiling except under unusual circumstances such as an episode of diarrhea or following the use of a laxative—a few patients in this group have rather tight structures two requiring occasional dilatation; (3) fair these patients must wear a perineal pad at all times because of unpredictable accidents, they have control of the bulk of the stool but there is a slight leak or staining on frequent occasions for this reason they are insecure without a pad; (4) poor in this category are carried those patients who have no control of the stools no sphincter and who have what amounts to a perineal colostomy. As judged by these standards the results were perfect 3 good 7 fair in poor 14.

The opponents of preservation of the anal sphincters firmly believe there is no place for such a procedure in the attack on cancer, their arguments are based on the assumption that such an operation cannot be sufficiently radical. If it is assumed from recent observations that lymphatic extension does not in general occur laterally along the levators or downward toward the skin and sphincters, there remains only the question of whether it is possible to secure a resection sufficiently high to remove involved nodes in the mesosigmoid. Whether or not it can be accomplished is determined by several anatomical variables. These variables can be judged only at the operating table with the abdomen open.

The authors' belief based upon experience with this series and the investigations of others is that such a procedure is applicable only to lesions whose lower margin is at least 6 cm. above the anal orifice and whose upper limit is at or below the peritoneal reflection. When the lesions are restricted within this field favorable results may be expected. If however enthusiasm for the procedure influences one to stretch the indications the value of the operation becomes lost. Even in patients who are required to wear a perineal pad the pursuance of daily activities is probably easier than for others with abdominal colostomies.

Thus it is believed that if cases are properly selected the operation of abdomino-perineal resection can be carried out and the anal sphincters preserved without jeopardizing the patient's chances of survival and with a very good chance of providing him with a functioning anal outlet.

HAROLD LUTTMAN, M.D.

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

Actinomycosis of the Liver with Recovery L. M. SNOWY. *Lancet* Lond. 1918, 1: 439.

The author states that no recovery from actinomycosis of the liver was recorded before 1914 and that few recoveries have been reported since that time. He cites a detailed history of a 9-year-old male patient who was saved through persistent and thorough treatment.

The patient had a 2 months' history of abdominal pain following an appendectomy. This prompted the performance of a laparotomy which disclosed actinomycosis of the liver. Within a period of 6 months an abscess developed in the abdominal wall and eventually there were numerous discharging sinuses. He had local and systemic penicillin therapy but on admission to the hospital a year after the laparotomy his condition was very serious.

A threefold method of attack was instituted. Surgical treatment consisted of free drainage, medical treatment consisted of blood transfusion, penicillin, sulfathiazol, potassium iodide and vaccine therapy. Radiotherapy included both radium and deep roentgen therapy. The latter was found to be the more practical. This strenuous therapy required 9 months but the patient made an apparent complete recovery and returned to school.

Serum Proteins in Hepatic Disease JAMES A. D. URMINEK and W. R. CAMPBELL. *Min. Cl. V. Amer. J.* 94: 3: 455

With use of the sodium sulfate salting-out technique for the separation of serum protein fractions as devised by Campbell and Hann, the authors demonstrate that characteristic disturbances occur in the serum protein of patients who have parenchymal diseases of the liver. By this means not only are the serum proteins separated into the recognized fractions, albumin, pseudoglobulin and euglobulin, but the presence in certain cases of an abnormal fraction, probably a globulin, is recognized. This abnormal globulin which is not present in normal serum is precipitated by addition of 13.5 per cent sodium sulfate. The authors have been particularly interested in this fraction and, for lack of a better name, refer to it as the "3.5 per cent fraction."

The normal average value of serum albumin is 5 gm. per 100 c.c. and of serum globulin just under 3 gm. per 100 c.c. The globulin fraction is divided into pseudoglobulin 1 and 2, which amounts to an average of 1.1 per cent, and the euglobulin fraction which varies from 0.6 to 1 per cent.

The serum protein disturbance is characterized by a rise in the serum globulin and by a more or less corresponding fall in serum albumin. The rise in serum globulin is largely accounted for by an increase in the euglobulin fraction, the pseudoglobulins being only mildly elevated. The elevation of the euglobulin fraction above normal is almost entirely due to the

appearance of the abnormal 13.5 per cent fraction, which may amount to 1 gm. or more per 100 c.c. in most cases of cirrhosis. The presence of this 13.5 per cent fraction in any quantity is abnormal.

This disturbance in the serum protein picture is much more marked in patients with diseases which affect primarily the parenchymal cells than it is in those in whom the hepatic symptoms are associated with other causes, such as invasion with secondary neoplasms or biliary tract obstruction. In acute hepatitis the disturbance is relatively mild. In the Laennec type of cirrhosis the abnormalities may be more pronounced. In the late cachectic stages of cirrhosis, however, all protein fractions are decreased.

A striking change in serum globulin was found in patients suffering from the various forms of extrabiliary jaundice or from secondary carcinoma of the liver, but to the patients with carcinoma a decided fall in serum albumin level was a frequent finding. These findings of hypalbuminemia, hyperglobulinemia, and the presence of the "13.5 per cent fraction" may assist one in arriving at a diagnosis of cirrhosis of the liver. LEE ELLIOTT LAY, M.D.

Diseases of the Pancreas. K. J. R. WIGHTMAN. *Med. Cl. V. Amer. J.* 1918 32: 518.

The anatomical features that must be borne in mind in discussing diseases of the pancreas are its relationships to the peritoneum, the bile duct, the duodenum, the splenic vein, the mesenteric vessels, the renal apparatus and the celiac plexus. The peritoneum covers the body and tail of the pancreas and is separated from the head by the duodenum and root of the mesentery, thus allowing inflammatory or neoplastic processes of the tail and body to become disseminated throughout the peritoneal cavity while those in the head involve the duodenum or bile ducts by compression or extension. Due to the intimate relationship of the pancreas to the celiac plexus and the somatic nerves of the posterior body wall, pain is a common and early symptom of all pancreatic diseases although there is no uniformity in character or distribution other than a tendency to be constant, boring, and to radiate to the back. In 50 per cent of people the pancreatic duct and bile duct are completely separate, in 2 per cent they form a common channel of significant length and in the remainder the ducts join together in such a way that simultaneous obstruction of both may occur with little possibility of producing a common channel to allow reflux or secretion from one to the other. The lymphatic drainage of the head is to subpyloric lymph nodes while the body and tail drain to nodes along the borders of the gland.

The pancreatic juice is secreted at a variable rate and with a variable content of enzymes, and is greatest in amount 1 to 3 hours after meals. The amount of secretion appears to be in excess of the requirement, for a very gross reduction is necessary before symptoms of pancreatic insufficiency are produced. Experimental obstruction of the pancreatic duct causes a rise in blood amylase and lipase content.

The pathological reaction of the pancreas in acute affections of various kinds is rendered uniform by the activation of trypsinogen and the subsequent digestion of tissues producing edema, necrosis and hemorrhage. The condition may then become self-perpetuating and progressive even if the original stimulus has been removed. The fundamental problem appears to be the means whereby trypsinogen becomes activated to form trypsin—what this means is has not been found. The amount of damage produced depends on the volume of juice which escapes, the concentration of enzymes in the juice and the number of large blood vessels with which it happens to come in contact. The damage may range from transient edema to massive necrosis. Progress may be continuous or intermittent and may become arrested at any stage. Secondary infection may supervene producing a suppurative process which may lead to abscess formation. The necrotic tissue may liquefy giving rise to pseudocysts. In the absence of any of these complications the necrotic tissue is removed, there is some regeneration of acinar tissue but a certain amount of fibrosis always takes place. Extreme fibrosis with reduction in the amount of glandular tissue, distortion of the ducts and the formation of cysts characterizes the condition known as chronic pancreatitis.

Calcification within the gland substance or ducts is a common late sequel. Chronic pancreatitis may be produced as a result of repeated attacks of acute pancreatitis or may be due to a steady progressive lesion. Cholelithiasis occurs in more than 50 per cent of patients with pancreatic disease as compared with an incidence of from 10 to 20 per cent in normal people of comparable age groups.

The syndrome of surgical shock which occurs in some cases of pancreatic necrosis is probably due to the presence of autolyzed tissue in the retroperitoneal space, and partly by reflex disturbances mediated through the numerous nerves in this region. The syndrome of chronic pancreatic insufficiency which is rare is characterized by fatty diarrhea, malnutrition and weakness, hypotension, hypoproteinemia, glossitis, clubbing of the fingers, vitamins D and K deficiency and disturbances in electrolyte metabolism. The best criterion of excessive fat loss is the demonstration that the daily total excretion of fat exceeds 20 per cent of the dietary intake.

The serum amylase test is of value when acute damage to the pancreas has been produced. There is a rapid rise within a few hours and a fall again to normal in 24 to 48 hours. In chronic disease the serum amylase is usually normal.

Acute pancreatitis occurs in a wider age spread than is commonly believed, obesity is not necessarily present, and the sex distribution is impartial. The subjective characteristics of the attack are variable, pain ranging from agonizing and steady to mild and remitting. The syndrome of shock which is traditionally associated with this illness is absent twice as frequently as it is present. The presenting picture on physical examination varies from the complete

picture of peritoneal inflammation with vomiting and distention to mild abdominal complaints. Laboratory findings too are variable although the white count is nearly always elevated. Serum chlonides are usually low and the finding of albumin in the urine is common. Recent workers have noted a lowering of the calcium protein and prothrombin content of the blood during an acute attack. The serum amylase is elevated for 12 to 48 hours and then falls. If the diagnosis is made with certainty these patients are not operated upon and in those who are operated upon, closure is accomplished without drainage or interference with the biliary tree unless there was an indication for doing one of these things. Medical measures include gastric suction, the administration of saline and glucose intravenously, transfusions of blood and plasma with sedation as required.

There is a group of patients who may be seen repeatedly with what appears to be attacks of acute pancreatitis. This condition recurrent pancreatitis is characterized by the development of a chronic lesion of increasing severity. In the intervals between attacks the patient is well or may complain of dyspepsia. Cystic changes and calcification occur with the development of the syndrome of pancreatic insufficiency. Occasionally pancreatic lithiasis develops.

Pancreatic insufficiency may occur in infancy. This syndrome of congenital fibrocystic disease appears to be congenital and even familial. The infant soon dies of malnutrition. If not he develops pulmonary infection with fibrosis, bronchiectasis and patchy atelectasis and dies before the teens are reached. Examination of the pancreas shows the acinar tissue to be replaced by fibrous tissue or fat. Treatment is the same as in adult insufficiency.

True cysts of the pancreas are rare. They may be neoplastic, or may be a collection of fluid which develops following acute pancreatic necrosis. This cyst has no epithelial lining and therefore is spoken of as a pseudocyst. Its fluid contains altered blood and pancreatic enzyme. The symptoms vary but examination usually reveals the presence of a cystic mass in the abdomen. The treatment is surgical and usually consists of evacuation and marsupialization. Excision of the cyst is attended by a higher mortality, frequently followed by the formation of an external fistula. The loss of pancreatic fluid via a fistula may cause a marked disturbance of electrolytes leading to impairment of renal function with nitrogen retention. Surgical therapy tends to be disappointing and should not be undertaken until the fistula has been given every opportunity to close spontaneously.

Carcinoma may arise from the acini, the ducts or (rarely) the islet tissue. The symptoms are largely determined by anatomic factors and show considerable variation. Pain and jaundice are the two most common symptoms. The tumor most commonly arises from the head of the pancreas. Carcinoma arising from the body and tail tends to become more widely disseminated. Curative therapy does not yet

appear to be within reach although advances are being made in the field of radical surgery. In patients in whom itching becomes intolerable a short circuiting operation should be considered.

FLY ELLIOTT LAFARRE, M.D.

Observations in Pancreatic Surgery. Acute Hemorrhagic Cystic, and Pseudocystic Pancreatitis. (Osservazioni di chirurgia pancreatica. Pancreatiti acuta emorragica, cistica, pseudocistica.) MATTEO BUCALINI. *Arch Ital Chir.* 1947 69 44

The author presents 5 case reports of varying forms of pancreatitis. The first, diagnosed perforated peptic ulcer was found to be an acute hemorrhagic pancreatitis. Cure by tamponade and partial closure of the wound resulted in improvement. The wound closing on the seventh day by second intention after the tamponade was removed.

In the second case, tumor of the pancreas of an adult, healed in the left hypochondrium. This was diagnosed as a calcified peritonitis following perforated ulcer. At operation a large cyst containing 1,000 c.c. of hemorrhagic serous fluid was found. This was aspirated and drained by means of rubber tube. Drainage ceased after period of 6 months.

After several days of pain and vomiting the third patient was found to have palpable masses in the epigastric region about the size of a fetal head at term. Radiologic examination revealed extrinsic pressure along the greater curvature of the stomach by the palpable mass. The preoperative diagnosis of pancreatic cyst was confirmed at operation. The cyst was marsupialized with gauze packing. The wound was completely healed in a month.

The fourth case occurred in a patient who received an injury resulting in three fractured ribs. This was followed by abdominal pain and vomiting which persisted. The patient lost about 12 kgm. in a month. A mass was palpable in the epigastric region but did not move with respiration and the stomach was displaced to the left by a mass compressing the lesser curvature and causing relative stenosis. These findings were made by means of roentgenography. A probable diagnosis of pancreatic cyst was made which was confirmed at operation. The cyst contained about a liter of yellowish fluid. A part of the cyst was resected. The residual sac was then sutured to the lesser omentum and the parietal peritoneum and the cavity was packed with gauze. The condition of the patient, which was poor before operation, became worse and death occurred on the third day.

The fifth patient had been having epigastric distress for 15 years. Examination revealed a large mass in the right hypochondrium, which moved with respiration. Roentgenograms revealed the tumor to be probably pancreatic in origin. At operation a retroperitoneal tumor covered by a fibroepithelial ligament and voluminous veins was found. About 650 c.c. of milky fluid were aspirated. An attempt at enucleation of the cyst proved unsuccessful and it was then marsupialized the edges being sutured to

the parietal peritoneum. The drainage ceased after 40 days when the wound was almost healed.

The author reviews the literature on the subject and brings out that in the early cases early operation is considered the essential element of success. According to the statistics of Linder (1917) of cases in which intervention was late the mortality was 62.5 per cent. and in cases in which it was early the mortality was 13.5 per cent.

When biliary calculi are found cholecystostomy is a lysalid in order to prevent bile reflux into the canal of Wirsung.

In 4 of the cases external drainage was used. The author classified these as one of prepancreatic encysted hematoma, 2 of pseudocyst and 1 of true cyst of the pancreas.

The question of internal drainage as advocated by some authors is discussed. The conclusion is establishing a communication between the cyst and the digestive tube is indicated in order to prevent the development of persistent fistula, so often encountered when cysts are marsupialized. The reason why some cases heal and others form a fistula is explained by Okincsev. The cysts which do not have a communication with the pancreas at the time of operation go on to heal, whereas those which still have a communication with the duct of Wirsung or its large tributaries will form a fistula.

The author concludes that as a primary procedure internal drainage is not without danger as there may be complications because of technical difficulties, hemorrhage, insufficient drainage, and secondary infection from the bowel. He advocates that the cysts be marsupialized and then, if a fistula should develop and refuses to heal internal drainage be performed by using the fistulous tract and anastomosing the cutaneous opening with an abdominal organ.

LEON J. PROBERT, M.D.

Radical One-Stage Pancreaticoduodenectomy. CASTELL G. CHILDS, III. *Surgery* 1947, 3 49

The purpose of this report is to review an operation for one-stage pancreaticoduodenectomy which proved satisfactory in a group of 22 patients operated upon at the New York Hospital during the past 6 years.

The author describes in detail his step-by-step technique for this procedure. The initial features of the operation are the maneuvers directed toward determining if possible whether or not the superior mesenteric vein is compromised by tumor. It can be hoped that eventually some successful method of avoiding the necessity of preserving this structure may be devised for it is certainly the weakest point, as well as the most frustrating, in the entire operative technique upon pancreatic cancers.

The author's technique is essentially that of Whipple. A choledochojejunostomy and a gastrojejunostomy distal to the biliary anastomosis is accomplished. With the use of this procedure the troublesome ascending cholangitis in the postoperative period is apparently avoided.

Reconstruction of the enteric canal is accomplished by retrocolic end-to-end pancreaticojejunostomy, retrocolic end-to-side choledochojejunostomy or simple implantation of the common duct into the jejunal lumen and antecolic long loop isoperistaltic gastrojejunostomy. As safety measures the retroperitoneal space, which it is impossible to reperi-tonize, is drained through a stab wound in the flank and a cholecystostomy tube is inserted through a separate stab wound just below the costal margin.

HAROLD LAUTMAN M D

Total Pancreatectomy EUGENE A. GASTON N
England J M 1948 238 345

The author reports a case of diffuse carcinoma of the pancreas in which total pancreatectomy was performed and analyzes 16 similar cases reported in the literature. The surgical results and physiologic changes are discussed. In the present case the spleen, the pyloric antrum of the stomach, all of the duodenum, 15 cm. of the jejunum, the lower half of the common bile duct and the right half of the transverse colon were removed in addition to resection of the entire pancreas. In 17 cases in which total pancreatectomy was performed for all causes 7 patients survived the operation and 10 died an operative mortality of 59 per cent.

The diabetic state that follows total pancreatectomy in man appears to be relatively mild. A state of apparently increased sensitivity to insulin has been present during the early postoperative period in nearly all reported cases. These observations are of great importance in the management of patients after total pancreatectomy. Hypoglycemic reactions should be avoided and treatment should be directed more toward the prevention of ketosis than to the control of the blood sugar levels.

Although material concerning the effects of total pancreatectomy on the liver in man is scanty it is evident from this review that the gross fatty changes noted in depancreatized dogs have not been observed either clinically or at autopsy. Changes similar to those seen in the dog and responding to the administration of lipocaine have been observed in spontaneous diabetes and after destruction of the pancreas from repeated attacks of acute pancreatitis. Therefore it is unlikely that the failure to observe in man the liver changes noted in the dog is due to a species immunity although this factor must be considered. It is more probable that the presence of choline and other lipotropic substances in the diet of man is sufficient

to protect the liver. Because of poor fat digestion in the total absence of pancreatic secretion the stools tend to be bulky and frequent these changes being more marked the higher the fat content of the diet. For this reason the postoperative diet should be low in fat, the caloric intake being maintained with carbohydrates which are well tolerated. In addition pancreatin in doses of 15 gm. daily should be administered to increase the absorption of fat and protein and to aid in the maintenance of nitrogen equilibrium.

JOHN L. LINDBQUIST M D

MISCELLANEOUS

Strangulated Obturator Hernia. ANDREW M. DESMOND and FRANK HUTTER. *Brit J Surg.*, 1948, 35 318.

Two cases of strangulated obturator hernia in which the correct diagnosis was made preoperatively are reported. The salient features which indicate the condition are: a combination of acute intestinal obstruction with pain referred down the front and inner aspect of the thigh to the knee in an elderly wasted woman; tender swelling palpable on the lateral pelvic wall by rectal or vaginal examination; tenderness within Scarpa's triangle which may sometimes be associated with a fullness or a well-defined lump; maintenance of the limb in a semiflexed position and limitation of hip movements because of pain. Differentiation from femoral hernia depends upon the fact that the fingers may be pressed down on the pubic ramus above the lump without discomfort.

The importance of correct preoperative diagnosis lies in the advantage of the proper choice of operative approach. A lower midline incision with the patient in the Trendelenburg position provides quick and easy access to the sac without unnecessary manipulation. The strangulation is almost always of the Richter type so that gut resection is seldom necessary. A partial resection of the bowel wall or the turning in of an area of doubtful viability is all that is required in most cases. Whether or not the sac itself should be removed or some form of repair carried out depends largely upon the general condition of the patient. The authors believe that this should be limited to the minimum operative procedure and that removal of the sac only should be adequate. The intimate relation borne by the bladder to the neck of the sac is of importance.

JOHN L. LINDBQUIST M D

GYNECOLOGY

UTERUS

Studies on the Histopathological Diagnosis in Biopsies of the Mucosa of the Corpus Uteri (Considerazioni sulla diagnosi istopatologica nelle biopsie della mucosa del corpo dell'utero) I. CURVO. *Fel. gyna.*, Geneva, 1946, 41, 265.

The author discusses the physiological and pathological tenets as applied to the uterine mucosa, stating that with the advent of Opitz, Hiltchmann, and Adler endometritis became an entity while the glandular form has been described as a functional state of the uterine mucosa. Some authorities however still believe that there are cases in which the glandular alterations are the result of inflammation and therefore this also must be considered an entity *per se*. To prove this, in 1910, he had E. Rossi study uterine scrapings. The latter came to the following conclusions:

1. The presence of plasmazellen may be of help in the anatomical diagnosis of inflammation but should not be credited with the importance given to it by Adler and Hiltchmann.

2. Permanent changes of the uterine mucosa must be considered pathological.

3. In doubtful cases certain histological characteristics must be taken into account in addition to the anamnesis before it is concluded that the changes are due to menstrual modifications of the mucosa.

4. Glandular endometritis is an entity because of

a. Changes as mentioned

b. Its presence in women already in the menopause with steady bleeding for successive months.

c. Changes concomitant with the inflammatory processes designated by the plasmazellen

The author states that these conclusions are true today if we add to them the dysfunction of the internal secretion of the follicle of the corpus luteum, and of the hypophysis as regulator of the menstrual cycle.

In 1909 Pankow suggested that uterine loss of blood may be due to ovarian dysfunction. R. Schroder explained how persistence of the ovarian follicles, by causing cystic hyperplasia of the glands of the uterine mucosa, led to uterine bleeding; while Keller described four types of uterine mucosa, namely (a) cystic glandular hyperplasia (b) atrophy of the mucosa (c) mucosa at rest and (d) glandular hyperplasia as in myoma.

The treatment as explained in the works of Kaufman and Giesen and pursued at the Gynecological Clinic of the Charité in Berlin (1940) corroborated the truth of the hypothesis of Pankow and Schroder.

This article is a review of uterine scrapings studied during 3 years for the purpose of correlating the morbid forms and histological changes in the uterine

mucosa. Cases of abortion were excluded. An accurate report of 401 cases with their clinical and histological data which the author studied is given. 198 cases presented characteristics of interstitial endometritis and 203 cases glandular hyperplasia. Among the latter he includes a few cases of uterine fibroma.

The author admits that the ovarian hormone plays an important role in the changes of the uterine mucosa. He discusses and confirms the work of Cova, stating that the uterine mucosa must be considered different from the mucosa of other tissues, and that the monthly desquamation and regeneration point to the existence of other stimuli, in addition to the action of hormones which favor glandular development or maintain the hypertrophy and hyperplasia caused by ovarian stimulation. According to the author this seems confirmed by his cases of fibromyomatosis in which the extensive glandular development conveyed the idea that he was dealing with cases of benign adenomas.

Menstrual cycle, menstruation, rupture of the follicle, and corpus luteum formation do coincide chronologically but only approximately. This is confirmed by Schickels (1931) Vignes (1939) and Hiltchmann. Adler and Temersvary, the latter reporting that in only 9 of 141 cases did the histological findings coincide with the phase of the menstrual cycle. The author emphasizes the fact that in the literature there is an abundance of cases in which menstruation occurred without the dehiscence of the follicle. His own cases are grouped as follows:

1. Changes observed in women already in the menopause. The study of the uterine mucosa of 137 women in the menopause and with amenorrhea ranging from 2 to 5 years in 67 cases from 5 to 10 years in 31, more than 10 years in 27 (2 women aged 80 and 87 years respectively being 40 years in the menopause) showed atrophy in 63 cases, moderate proliferation in 24, hyperplasia in 28 and retrogressive changes in 33. In 28 of the 43 cases with moderate proliferation and hyperplasia the mucosal changes had invaded the endometrium and the hyperplasia compared very well with that present in the age of fecundity. This supports the view of Novack, Yul and Vallart that the estrogenic function of the ovary may be observed in the advanced menopause and may be even reinforced by the estrogenic action of other glands of the genital chain.

2. Cases with polypoid formation of the uterine mucosa. According to Lahm polypoid formation is found only in women near the menopause and is due to altered ovarian function but according to the author it may be found at any age. The polyps are not to be regarded as originating from residue of the canal of Gartner or Wolff or the duct of Mueller but as an aftermath of inflammation leading to tumefaction which gradually becomes a polyp.

3 Decidual endometritis, i.e. cases of postabortion endometritis in which abortion had not been reported or had taken place so long previously that no clinical relation existed between the two conditions. The endometritis must be regarded as due to chronic irritation leading to endometrial changes which become manifest in the mucosa and which are not exfoliated during menstruation. Hormonal influence and chronic irritation may cause them to proceed to polypoid formation.

4 Cases in which the glandular development is so extensive that adenomatous formation must be considered. The author states that the glandular hyperplasia caused by chronic inflammation may proceed beyond the stage of physiological menstruation and assume the traits of an adenoma, and at times may even lead to a polypoid formation.

5 Uterine fibromas and uterine fibromatosis. The author confirms the microscopic findings described by Wider in 1878 i.e. whenever the fibromatous node projects or is close to the uterine cavity the mucosa is atrophic, and when the fibromatous node is distant from the uterine cavity the mucosa contains many glands which have a tendency to infiltrate the uterine muscle.

The author states that the glandular hyperplasia may be due to hormonal action or to the stimulus causing the fibrous neoplasm. In the cases of fibromyomas he detected in the ovarian parenchyma constant sclerocystic changes and serous follicular cysts and these, he says may influence the uterine mucosa and cause glandular changes. He advances the opinion that the fibromas may lead to malignant degeneration of the uterine mucosa and refers to a case he reported in 1946 in which a woman receiving x ray therapy for uterine fibromyomas developed an adeno-carcinoma of the uterus. Another opinion he advances is that the dense hyperplasia and glandular hypertrophy must be considered a precancerous condition.

The menorrhagia and metrorrhagia are ascribed to prolonged follicular action which causes endometrial proliferation glandular hyperplasia and capillary ectasia and to hyperactivity of the uterus which by causing hyperemia, will lead to metrorrhagia. The metrorrhagia in turn is enhanced by the lesser contractility of the uterus brought about by the presence of the nodules in the uterine parietes.

JOSEPH M. A. PARK, M.D.

The Treatment of Carcinoma of the Cervix with Radium and 800 Kilovolt X Rays. HERRAZET E. SCHMITZ. *Am J Obst* 1948, 55: 262

One hundred sixty-six cases of primary carcinoma of the cervix admitted to the Mercy Hospital Institute of Radiation Therapy Chicago, during the 10 year period through 1942 are reported. The cases are grouped according to the Schmitz classification of four groups, and are microscopically graded according to Broder's division into four grades. All cell types are treated with roentgen rays and radium and the Wertheim operation is reserved for lesions that

are refractory to irradiation or that recur. None of the patients in this series were treated by subsequent surgery because of recurrence.

The method of combined radium and x ray therapy is described. An x ray dose of 4,000 roentgens in to the tumor and surrounding gland bearing areas is desired. Whenever possible, but one anterior and one posterior field is used this field being 30 by 20 cm or less depending on the size of the pelvis. No special effort is made to screen out vital structures as this practice invites error due to misdirection of the radiation beam. Radium therapy is carried on in conjunction with the roentgen therapy. A total dosage of 4,500 mgm. hours is administered through the cervical canal. Roentgen therapy is relied on entirely to destroy extension of the disease beyond the zone of effective radium rays.

A 5 year relative cure rate of 43.37 per cent is reported and compared to a previously reported rate of 28.00 per cent in a group in which similar radium therapy but lower voltage roentgen rays were used. The improvement is considered due to the higher voltage roentgen therapy in present usage.

The technique of radiation as described varies somewhat from the most widely accepted procedures because of the method of applying radium and x rays and the dosages used. This has helped to avoid the numerous complications of bowel, ureteral and bladder injury described in many clinics and given by some as a most important reason for returning to surgical treatment.

The microscopic grading of tumors is an aid in predicting the response to therapy but not in determining the type of treatment indicated. A localized tumor irrespective of its cell type should be irradiated as in most instances it will respond satisfactorily. If it proves to be resistant to this form of treatment surgery can be instituted and executed without increased difficulty.

Of all cases only 22.2 per cent were clearly operable. Salvage in the cases in groups I and II was 70 per cent at the end of 5 years and 55 per cent at 10 years. This is higher than for any comparable surgically treated group. It is the author's decision therefore to continue treating all cervix cancers with irradiation and to employ surgery for the conditions as stated.

JOHN R. WOLFE, M.D.

The Evaluation of the Results of Carcinoma of the Cervix Uteri Treated by Radical Vaginal Operation. SUPORN MITRA. *Am J Obst*, 1948, 55: 293

The rationale of the treatment of carcinoma of the cervix is still a controversial subject. Although the general trend of opinion is in favor of radiation therapy the surgical treatment still occupies a definite place in its management. An analysis of world statistics shows that whatever method is followed (operation or radiation) the end results are for all practical purposes the same in the hands of experts with a small percentage of variation.

The author began using the radical vaginal operation in 1932 supplemented by postoperative radia-

tion. Reasons for using this procedure instead of radical abdominal operation are given. Special points of technique are given in detail. Cases are classified according to the League of Nations formula. Materials for operation were taken not only from grades 1 and 2 but also from grade 3.

The report concerns 151 patients, 6 of whom died as a result of operation, the primary mortality being 3.8 per cent. The total number of patients operated upon between 1933 and 1940 was 93. Five year salvage cases totaled 35 i.e. a relative 5 year cure rate of 37.6 per cent. The cases are arranged in groups, with their corresponding survival rates, and the author compares these figures advantageously with similar groups treated in earlier years by radiation therapy.

The author states that as yet there is no remedy for advanced cases. Operable cases yield satisfactory results up to a certain limit whatever method is followed provided that treatment is given efficiently and with meticulous precision. It is only by the detection of early cases and the centralization of patients in special cancer clinics that we can markedly improve our end results and hence the right movement should be that of education of the lay public and special courses of training for general medical practitioners. JOHN R. WOLFF, M.D.

Lat. Recurrence of Cervical Carcinoma following Radiation Therapy HAROLD SPERRY, M.D. Oid. 945 35 533.

More than one half of the patients with carcinoma of the cervix who have been unsuccessfully treated by irradiation at the Roosevelt Hospital, New York, showed a recurrence of their tumor within a year following treatment. The average interval between treatment and recurrence in 105 patients with recurrent epidermoid carcinoma of the cervix treated with radium was 14.5 months. Tumor recurrence after 5 years is distinctly unusual, only one occurring in the above group. This fact has served as the justification for the reporting of cervical cancer statistics in terms of 5 year cures. Most gynecologists consider patients completely cured who survive this period with no clinical evidence of the disease.

Cervical cancer does not always run so rapid a course however. New concepts of its pathology and biology of the early stages of the disease have been developed during recent years. Lesions which formerly were considered benign or of questionable malignancy have been associated with genuine cancer sufficiently often either by observation of the untreated patient during the ensuing years after biopsy or by more intensive examination of the original specimen to merit the diagnosis of cancer themselves.

The purpose of this communication is to record extraordinary cases which show that cervical carcinoma may progress slowly or perhaps even lie dormant for long periods after treatment by irradiation, during its later clinical stages. The case histories are given indicating local recurrence of previously irra-

diated cervical cancer 17.5 years and 19.5 years later respectively.

The author concludes that from a practical clinical standpoint it would seem safe to consider as probably cured any patient with cervical cancer who survives the standard 5 year period without evidence of recurrence. JOHN R. WOLFF, M.D.

ADnexal and PerIuterine Conditions

Thecoma—Xanthomatosed Thecocellular Fibroma of the Ovary of Loeffler and Priesele—Mösenchymoma of the Ovary of Novak (Thecoma—Fibroma thecocellulare xanthomatodes ovarii de Loeffler e Priesele)—mesenchimoma do ovário de Novak. CACIO WATAMANE and ANTONIO NASARETH. A. Brasil. gin. 947 24 433.

The histogenesis of thecomas is not yet definitely established. Their incidence amounts to 3 or 5 per cent of the solid ovarian tumors, and over 70 per cent of them occur after the menopause. The appearance of metrorrhagia in this period associated with a palpable ovarian tumor and hyperplasia of the endometrium, suggests the presence of a tumor with hormonal activity.

The occurrence of metrorrhagia is nearly twice as frequent in the postmenopausal cases as in the cases encountered during the menopause. The presence of tumor before the menopause generally produces changes in the menstrual rhythm. Few patients complain of rapid abdominal enlargement due to the tumor however the tumor may cause signs of compression, intestinal occlusion, and an acute condition of the abdomen by torsion of its pedicle. Hyperplasia of the endometrium is present in 30 per cent of the cases and consists of thickening with polypoid aspect. The uterine body also increases in size, principally in the form of myomatous nodules. Amenorrhea is the most frequent symptom in young patients and may be primary or secondary, the latter form predominating. Sterility is less frequent. Development of breast atrophy, revivification of the vaginal mucosa, and even appearance of libido may be observed in menopausal cases. Association of adenocarcinoma of the endometrium and thecoma is relatively frequent. Virilization is rarely observed. Ascites and hydrothorax may be found.

The thecoma is always unilateral and usually on the left side. It has a predominantly estrogenic action. Macroscopically it has the aspect of a solid ovarian fibroma. Its surface is smooth or nodular of white-yellowish color with grayish tints and sometimes dark spots which are due to hemorrhagic foci. It is generally free from adhesions. Its size varies greatly. It may escape the most careful gynecologic examination but its average size is that of a hen's egg. Section reveals a yellowish or grayish surface composed of foci of varying size and enveloped by a fine capsule. Microscopically there are cords of large fusiform cells arranged irregularly, interlaced through the tumor, and separated by bundles of connective tissue of variable size. The cells have a rather indistinct membrane

and a well stained nucleus. Sudan III staining reveals characteristic intracellular fat and some extracellular fat globules, which are birefringent. In addition there are also large cells filled with lipid which are intensively thecal cells. Silver impregnation shows the presence of a reticulum.

Thecomas are regarded as benign tumors but there are some which evolve in a malignant manner. However metastasis to neighboring or distant organs has not yet been observed. Clinical diagnosis of thecoma is difficult. Only histologic examination can furnish the correct diagnosis by revealing the presence of the intercellular reticulum and of birefringent fat. Treatment is always surgical. Bysterecotomy with bilateral salpingo-oophorectomy in women beyond or near the menopause or simple extirpation of the tumor with or without unilateral salpingo-oophorectomy in young women.

The authors report a case in a woman of 19 years who for about 2 months had diffuse abdominal pains, principally in the hypogastrium, and was suspected of being 3 months pregnant. A plain film of the abdomen did not reveal any shadows denoting pregnancy. In about 2 months she developed marked cachexia and an enormous ascites. Infraumbilical laparotomy disclosed a tumor which occupied the entire hypogastrium, extended into the right iliac fossa, and was easily removed. The condition of the patient was good on the eighth postoperative day but peritonitis developed suddenly and resulted in death. The tumor weighed 3 kgm. and consisted of various nodules of different size solidly grouped together and all having more or less the same aspect of yellowish color and firm consistency some showing dark spots on their surface. The histologic diagnosis was tumor of the thecal and granulosa cells in which the first variety predominated over the second.

RICHARD KEMEL, M.D.

Malignant Tumors of the Ovary JOHN B. MONTGOMERY 4m *J. Obst.*, 1948 55 301

This study consists of a brief review of all of the cases of malignant disease of the ovary that were treated in the Division of Gynecology of the Department of Obstetrics and Gynecology at the Jefferson Medical College Hospital Philadelphia between October 1, 1921 and October 1, 1946. Of 107 cases 84 were primary carcinomas of the ovary and it is with this group that the article is chiefly concerned.

The cases were studied in the light of the four outstanding factors that generally are regarded as governing the end-results in ovarian carcinoma: the extent of the growth or the operability, the grade of malignancy, the histologic type of tumor and the influence of x-ray therapy on the lesion. Throughout the study when possible it is attempted to show the interrelationship of these factors.

A summary of the end results shows that the 5 year survivors amounted to 22 per cent of the entire group of patients which approximates the 30.5 per cent of survivors in the primary adenocarcinoma group.

Operability and grade of malignancy are undoubtedly the factors that govern the percentage of survivals for 5 or more years. So far as type goes the papillary cysts are the most favorable and if they are completely operable one may safely predict that at least 50 per cent of the patients with this condition will be alive and free from disease for more than 5 years. On the other hand the number of 5 year survivors among the patients who have actively malignant tumors, the partly cystic and partly solid type or the solid type is pitifully small. This result is influenced by the fact that the vast majority of such tumors do not come under observation until the growth is far advanced.

The difficulties in achieving an early diagnosis in carcinoma of the ovary seem almost insurmountable. Many are "silent" or nearly so. Yet in the present study 37 per cent of the patients had abdominal symptoms mostly referable to the gastrointestinal tract for from 6 months to several years before a pelvic examination was made.

If malignant disease is to be detected at an early stage in more than an occasional patient, routine periodic pelvic examinations will have to be carried out in large numbers of women supplemented at times by special studies and occasionally by an exploratory abdominal incision. The success of such a program will depend upon the ability and care of the family doctor as well as the gynecologist.

JOHN R. WOZNY, M.D.

Abdominal Contusion and Rupture of Pyosalpinx into the Free Peritoneal Cavity (Contusione addominale e rottura di piosalpinge in peritoneo libero) FRANCO ROBELLO *Riforma med.*, 1947 61 536.

A case report of traumatic rupture of a pyosalpinx into the free peritoneal cavity is reported. This occurred in a 20 year old female who 2 months previously had had irregular treatment for hlenorrhagia (gonorrhoea). There were no intervening symptoms to indicate the possibility of salpingitis or pelvic peritonitis. She received a violent human kick in the hypogastric region during an altercation. This was followed by a violent pain in the lower abdomen followed by collapse. This pain persisted and was followed by vomiting. She was seen by a surgeon who noted the abdominal contusion with a normal temperature and slight muscle spasm and he decided to observe the patient. Next morning however she was brought to the hospital with a classical picture of diffuse peritonitis caused by perforation of a hollow viscus.

There was painful limited uterine mobility with a pasty feeling of the organ.

With a diagnosis of perforated viscus the patient was operated upon under morphine scopolamine ether anesthesia. Considerable pus was encountered. The appendix was hyperemic and adherent to the cecum and distal loop (ileum). Appendectomy was performed. On the left side was noted a large pyosalpinx about the size of a small cucumber adherent to the sigmoid colon and with an anterior laceration

from which was exuding pus. The right adnexa presented slight tumefaction with no discharge of pus. The left adnexa were excised, the spillage aspirated and closure with a Mikulicz tube was performed but only partial closure was made of the layers of the abdominal wall. The patient was given glucose by hypodermoclysis, vitamin C, cardiotonics, and penicillin 50,000 units every 3 hours up to a total of 900,000 units. The condition gradually improved and drainage ceased by the eighteenth day.

The author believes that undoubtedly the trauma was responsible for the rupture. He thinks that this is a rare case for among the thousands of patients with abdominal contusion operated upon at the Pellegrini Hospital no similar lesion was previously reported.

A review of the literature is presented. Among the recommended treatments are simple drainage with a rubber drain or a Mikulicz tube, excision of the adnexa, unilateral or bilateral hysterectomy total or subtotal. The author believes that surgery should be limited to the cases in which it is indispensable that the cause of the peritonitis should be removed and abdominal drainage should follow. The more formidable procedures, such as hysterectomy, are not recommended in the presence of peritonitis even though the patient may be operated upon early and in good condition.

LOCLAN J. FROMMELT, M.D.

Nodular Fallopian Tubes (Trompas nodulares)

M. TELER PACHECO ULLAO. *Bol. Soc. chilena obst. gín.*, 1947, 7.

The author has made a clinical and anatomopathologic study of 20 complete tubes and 4 tubal stumps surgically removed from 15 patients. The lesions were found in the isthmus portion of the tube in 66.6 per cent and in the interstitial portion in 33.3 per cent. Often the tube was diffusely enlarged and presented various nodules which could be seen and felt; they were round, hard smooth generally free (without adhesions to the neighboring structures) and had the same color as the rest of the tube. Their greatest diameter was 1.5 cm., but the usual diameter was 0.5 cm. They were bilateral in 53.3 per cent of the cases. The nodules were due to diverticulosis in 53.3 per cent of the specimens, to tuberculosis in 33.3 per cent, and to nonspecific chronic salpingitis in 13.3 per cent.

The characteristic morphology of diverticulosis of the tubes, also called "tubal adenomyosis," is the presence on the entire inside of the enlarged segment, of numerous diverticuli which are lined with glandular epithelium of tubal type (endosalpingiosis) or endometrial type (endometriosis). In the present series endosalpingiosis was present in 33.3 per cent and endometriosis in 20 per cent.

The collections of glandular epithelium form irregular alveolar spaces, uniformly distributed in the muscular layer from the mucosa to the serosa and separated only by a small amount of muscular tissue. The entire wall is changed into a veritable honeycomb of spaces. Often the lumen of the tube is much

decreased in the region of the diverticulosis and may be completely closed distal to it. The alveolar spaces vary in size and form; sometimes they are empty while at other times they contain a thick fluid, blood, desquamated epithelial cells or macrophages. In case of endosalpingiosis the secondary cavities do not have a stroma but are lined by tubal epithelium which lies directly on the musculature. In case of endometriosis there is an undifferentiated mesenchymatous tissue similar to the stroma of the endometrium inside of the musculature, which surrounds the alveolar spaces lined with typical endometrial glands having a high cylindrical epithelium with or without signs of secretory activity.

Whether the lesion is produced by inflammation or is of congenital origin is still under discussion. Of 8 patients with tubal diverticulosis, only 2 had previous pelvic inflammation and none showed histologic traces of inflammatory infiltration. On the other hand, 3 patients presented congenital anomalies (hypoplasia of the genital apparatus, vaginal atresia and rudimentary double uterus and uterus bicornis) which supported the theory of congenital origin.

The symptomatology was masked in all cases by that of the other gynecologic disorders which led the patients to surgery; but in 75 per cent there was an intense and progressive premenstrual and menstrual dysmenorrhea accompanied by hypermenorrhea and a high incidence of prolonged periods of sterility.

Tuberculosis of the tubes was bilateral in all cases and there was primary sterility in 80 per cent. The ages of the patients ranged from 20 to 37 years. The fibrocystic or caseous nodules in the wall of the tube presented the typical rotary aspect. In most cases there was also a secondary endometrial tuberculosis.

Non specific chronic salpingitis was bilateral in all cases and histologic section showed strong inflammatory infiltration with small intraparietal abscesses, atrophied mucosa, and greatly reduced lumen. All of the patients were sterile.

Women in whom the problem of sterility must be taken into account should be given conservative surgery which in most cases will consist of tubal implantation into the uterus after resection of the involved portion even when the tube is permeable. Women in whom it is not necessary to consider this problem should be treated radically. Tuberculosis tubes must be completely extirpated irrespective of the age of the patient; this is generally associated with subtotal hysterectomy. Tubes with nonspecific chronic infection should be removed with or without associated hysterectomy.

RICHARD KEMEL, M.D.

EXTERNAL GENITALIA

Prolapse of the Vaginal Vault following Hysterectomy: A New Method of Repair. HENRY N. SHAW. *West. J. Surg.* 1948, 56, 7.

An operation to correct prolapse of the vaginal vault by the use of fascial strips is described. A midline incision is made and the peritoneal cavity is opened. Fascial strips 2.5 cm. wide are dissected

from each side of the midline incision in the rectus fascia. A catgut suture is placed deep in the posterior surface of the vaginal vault or cervical stump after it has been isolated in the peritoneal cavity.

A curved Kelly clamp is passed between the rectus muscle and peritoneum to the internal inguinal ring. The clamp is now passed beneath the peritoneum following the course of the round ligament and down to the catgut suture. The clamp enters the peritoneal cavity at this point grasps the end of the suture previously introduced into the vault of the vagina and draws the suture out to the surface through the internal inguinal ring. The catgut suture is tied to the upper end of the fascial strip which is then drawn back into the peritoneal cavity along the tunnel created by the Kelly clamp. The fascial strip is now sutured to the posterior surface of the vaginal vault or cervical stump with a silk suture. The procedure is repeated on the opposite side and the abdomen closed in layers.

Since 1925 the author has had 22 cases of prolapse of the vaginal vault following hysterectomy. Nine patients were treated by removal of the cervical stump, when present, and extensive repair of an associated cystocele. Three patients were successfully treated by means of the operation described.

GEORGE BLUMICK, M.D.

The Treatment of Vaginitis with Penicillin Vaginal Suppositories. STUART ABEL and CHESTER J. FARMER. *Q. Bull. Northwest Univ. M. School* 1948, 32:5

Twenty patients suffering from various types of vaginitis were treated with cocoa butter suppositories containing 100,000 units of penicillin calcium. Smears and cultures were made prior to treatment. Seven of the group reacted positively for trichomonas vaginalis organisms. In the rest of the cases the organisms were of a nonspecific type.

The results of treatment of the patients suffering with trichomonas vaginalis organisms were disappointing and would seem to indicate that the treatment had little value. Douches were not used. The other patients, in whom cultures showed a variety of organisms of a nonspecific nature, all showed complete or nearly complete improvement.

The average dose of penicillin used in the treatment of this group was 900,000 units and the average duration of treatment, 11 days. The authors suggest that penicillin in the form of suppositories might be of benefit in the preoperative preparation and post-operative care of patients in whom extensive vaginal operative work is planned.

GEORGE B. BRADSHAW, M.D.

Vaginal Repair Combined with Vaginal Hysterectomy. E. HARRISON. *Am. J. Obst.* 1948, 55:403

Vaginal hysterectomy for repair of the vagina in varying degrees of prolapse presents distinct advantages over certain other methods of treatment of this affliction and yet this treatment is not commonly applied. Most of the literature on this sub-

ject to date lacks detail in description and passes over some of the important as well as some of the most difficult steps in the operation as if they did not exist. The author believes that this lack of detail may contribute to the fact that the operation is not performed more widely by gynecologists.

Removal of the uterus during the course of vaginal repair is indicated far more frequently than it is practiced. The operation presents distinct advantages in selected cases over any other form of treatment of procidentia and gynecologists in general should be encouraged to perform it.

The most important anatomical considerations are briefly outlined with reference for further detail to the recent publication *The Pelvic Floor in Parturition* by Richard Power of Montreal in *Surgery, Gynecology and Obstetrics* September 1946.

The indications and contraindications for vaginal hysterectomy in the repair of procidentia are discussed and the advantages and disadvantages of the operation are considered.

A detailed technique of operation is described and illustrated.

JOHN R. WOLFE, M.D.

MISCELLANEOUS

Presacral Neurectomy for Dysmenorrhea. FRANCIS M. INGLETON and JOE V. MIZICK. *N. England J. M.* 1948, 238:357

During the past 16 years the authors have performed 111 presacral neurectomies for the relief of dysmenorrhea. The patients were divided into two groups: those with essential dysmenorrhea and those with acquired dysmenorrhea. Complete relief was obtained in 81 per cent and partial relief in 4.5 per cent of the patients with essential dysmenorrhea. 14.5 per cent of these failed to obtain relief. In the group with acquired dysmenorrhea, complete relief was obtained in 52.6 per cent and partial relief in 21 per cent. In 26.4 per cent of these the operation failed. The etiology of acquired dysmenorrhea in the order of frequency was (1) endometriosis, (2) postpartum dysmenorrhea, (3) pelvic inflammation and (4) post-appendectomy dysmenorrhea.

An analysis of the cases in which presacral neurectomy failed to produce relief of essential dysmenorrhea revealed three possible causes for the failure: (1) psychoneurosis, (2) regeneration of sympathetic nerves and (3) incomplete sympathectomy.

In an attempt to eliminate the psychoneurotic patient the authors have devised a test which consists of preventing ovulation by the use of estrogen and then stopping the estrogen and allowing the patient to have withdrawal bleeding. Estrogen withdrawal bleeding or anovulating bleeding is painless in the normal healthy female. If this test is carried out and the bleeding is still associated with pain the authors believe that the pain may be psychic in origin and that presacral neurectomy is contraindicated.

The second possible cause of failure of this operation is regeneration of the sympathetic nerves. Re-

operation of patients in whom the first procedure failed demonstrated the regenerated nerves. The infrequency of regeneration following this type of sympathectomy may be due to the fact that such a long segment of nerve is removed that the widely separated nerve ends never rejoin.

The third possible cause of failure is an inadequate sympathectomy. The presacral nerve is a distinct nerve in only 5 per cent of the cases, therefore the anatomic variations may well account for some of the failures of this operation.

Twenty-four of the 31 patients have given birth to children since the presacral neurectomy was performed and labor was painless in 33 per cent of the patients.

Follow-up studies revealed that 7 patients with essential dysmenorrhea continued to have backache during menstruation and in labor. This is caused by the fact that all of the afferent fibers do not pass through the presacral plexus but pass transversely through the second, third, and fourth sacral segments and produce the referred backache.

The authors conclude that patients with essential dysmenorrhea obtain the best results and that patients with acquired dysmenorrhea have only a 50 per cent chance of obtaining relief from pain. The reasons for failure are discussed.

J. ROBERT WILLSON, M.D.

Clinical-Statistical Contribution to the Study of Tuberculosis of the Female Genitalia (Contributo clinico-statistico allo studio della tubercolosi genitale femminile). Livi, N. *Nobili Riv. Ital.* 1947 3: 253.

Seventy women with genital tuberculosis were subjected to surgical therapy in the gynecological and obstetrical clinic of the University of Bologna, Italy, during the period from 1936 to 1946. The author's material comprises 0.91 per cent of all gynecological admissions (7,653 cases) during this period. These patients were late in menstruating, 18.75 per cent did not menstruate until they were more than 6 years of age. Menstrual disorders were noted in 60 per cent of the patients, 40 per cent of these had amenorrhea or oligomenorrhea.

In the greater number of these patients (38.57 per cent) the condition occurred in the third decade of life. The material comprised 57 single and 43 married women. Of the married patients, 83 had never been pregnant, had suffered abortions, and 16 had borne children. The 16 fertile women had had an average of 1.7 children each.

In 59.37 per cent of the cases, a focus of tuberculous was present or had been present in other organs of the body. This does not mean, however, that in all of the other patients the genital lesion was primary. There were probably other primary lesions elsewhere which were not found, or had healed. The author believes that the descending route, that is, the peritoneum being first involved primarily was the commonest form of dissemination. There were only 5 instances of involvement of the cervix, with

the complication of a tuberculous salpingitis in 1 of these. In 4 patients the body of the uterus was the part affected, 1 of these had an associated tuberculous salpingitis, and 1 had a fibrocystic peritonitis. The internal orifice of the cervical canal seemed to form an insuperable barrier to the spread of the process. In 54 (77.14 per cent) of the patients the tube was the part involved. In 7 (11.96 per cent) of these there was an associated exudative peritonitis, in 27 (50.00 per cent) a fibrocystic peritonitis, and in 30 (37.03 per cent) the salpingitis was an isolated phenomenon. Of 19 cases of pyosalpinx, 14 were bilateral, 13 cases of nodular caseous salpingitis, 13 were bilateral. There were 4 patients with a simple tuberculous inflammatory salpingitis bilateral in 3. There were 2 cases of tubo-ovarian abscess. In addition, 13 instances of tubal infection were observed among those patients with uterine and ovarian involvement. There were 10 cases of tubercular involvement of the ovary (14.28 per cent) associated with a tuberculous salpingitis (in 3) and a fibrocystic peritonitis (in 7). In 7 cases the lesion in the ovary was monolateral, in 3 bilateral. As regards the involvement of the peritoneum in these genital lesions, there were 37 instances (52.85%) of fibrocystic tuberculous peritonitis and 7 (10.00%) of peritoneal abscess.

In the surgical treatment of the more severe conditions, spinal anesthesia was preferred. Subtotal hysterectomy and bilateral adnexectomy were performed in 45 patients, and a total hysterectomy and bilateral adnexectomy in 2 patients. In only 4 instances were the tubes and ovaries removed. In 2 patients both tubes and one ovary were removed. In 10 of these patients exploratory laparotomy revealed conditions contraindicating further surgical procedures. And in 5 patients the abnormal contents of the abdominal cavity were evacuated without attempting removal of the involved organs themselves.

In the complete series 1 patient died on the day of operation. Of the rest, 37 patients could be traced for periods of from 4 to 10 years. Five others have died, however, only after at least 2 years of normal life, usually at their original occupations. Of the remaining 33 patients, 18 recovered from the operation and have since remained without symptoms (optimum result) in 12 patients the results were good, that is, the mild ailments such as leucorrhea, castration phenomena, and vague pains were no worse than would be expected following any other type of gynecological operation. In 3 the results were mediocre and the patients complained of vague pains (ascribable to residual adhesions). There was 1 case of laparocoele, and 1 case of residual parietal fistula which developed following Mikulicz drain and required a year to heal.

These results show the high percentage of recovery (86.12%). The author ascribes this exceptional achievement to the fact that at Bologna surgeons are neither interventionists nor abstentionists, but they adopt an eclectic attitude toward the individual patient and consider whether to operate and what

type of operation would give the best result. Nevertheless they have never subscribed to the seductive theory that removal of the gravest tuberculous lesion may result in improvement or disappearance of the residual lesions; they have always attempted to carry the operation to the point of removing all of the diseased tissue unless stopped by some insurmountable technical difficulty. The patients are kept under close clinical observation and every resource is exhausted to detect any other focus of infection in the body and to evaluate the general condition and readiness for operation of the patient. This period of repose coupled with high calory and high vitamin diet, may be cut short by some urgent indication to operate. It may last for a week or longer. In one patient the period of observation lasted for more than 8 months before operation was attempted.

JOHN W. BRENNAN M.D.

In Vitro Fertilization and Cleavage of Human Ovarian Eggs. MIRIAM F. MENKIN and JOHN ROCK. *Am J Obst* 1948 55 440.

Most textbooks of embryology comment on our lack of knowledge of the fertilization and first cleavage stages of the human ovum. In 1939 Pincus and Saunders reported that about 30 per cent of human ovarian ova cultured in blood serum for intervals ranging between 8½ and 24 hours showed polar body formation and hence became theoretically susceptible to fertilization. On the basis of these findings the authors have made numerous attempts to initiate in vitro fertilization of human ovarian eggs cultured for varying lengths of time from ovarian tissue removed just prior to the expected time of ovulation.

Several factors were varied throughout the period of the study e.g. the conditions of culture of the eggs both before and after exposure to spermatozoa, the duration of contact of egg and spermatozoa and the concentration of the sperm suspensions used. Employing a certain combination of these variables the authors were able to induce cleavage in three experiments. In 2 of these cases the egg was found to be in the two-cell stage. In the third case two eggs divided but one part of the cytoplasm appeared fragmented and soon proceeded to undergo rapid degenerative changes. In the present report discussion is confined to the two eggs in the two-cell stage and the more normal appearing of the two eggs in the three-cell stage.

The authors report in detail the procedures involved in obtaining their specimens and in the culture and fertilization of the specimens. A complete series of stained sections of one of the eggs in the two-cell stage was obtained and is described. The egg in the three-cell stage was similarly prepared.

A photomicrograph of the stained section of the follicle from which an egg was obtained is presented and described. This follicle represents a typical 'preovulatory' stage i.e., a mature follicle that is just about to rupture. It is the only section in existence as far as is known of a human ovarian

follicle which can be exactly dated with respect to subsequent fertilization of the egg derived from it.

The time relations in these experiments are in general accord with those reported previously for the in vivo fertilized tubal monkey egg cultured in vitro as well as for in vivo fertilized mouse eggs studied at different intervals after copulation.

JOHN R. WOLFF M.D.

Pelvic Sympathocytoma (Simpaticotoma pelviana) S. DEXEUS. *Rev esp. Obst* 1947 4 395

This article reports the case of a 23 year old woman, a para III who suffered for 6 months with pain in the right iliac fossa. Bimanual pelvic examination showed the uterus to be in anteversion and displaced to the left. Both adnexa were normal. In the right iliac fossa however, there was an easily outlined mass, of the size of a hen's egg. The tumor was solid and smooth and appeared to be attached to the sacrum.

At operation the tumor was mobilized with ease from its sacral bed despite a traversing right ureter. A short pedicle facilitated excision *in toto*.

Microscopically the tumor consisted of nerve cells mated with connective and vascular tissue. The nerve cells were of the sympathetic ganglion type arranged in small clusters. The plexuses of the nerve fibers were very irregular. There was an abundance of pigmentation and the periphery of the tumor was composed of dense connective tissue.

The tumor was benign hence the prognosis was good particularly since removal was complete.

The author was able to find only 13 similar cases in the literature at his disposal.

STEPHEN A. ZITMAN M.D.

Injuries to the Bladder in Gynecological Surgery J. K. FENNEY. *Irish J Med Sc.* 1948 Series 6 113

Because of the normal intimate contact of the urinary bladder and the uterus and also the structural changes resulting from uterine and adnexal disease it is to be expected that bladder injuries will some times occur in the course of abdominal and vaginal gynecologic operations. The author considers various pitfalls and suggests ways of minimizing their occurrence.

BLADDER INJURY IN ABDOMINAL OPERATIONS

Incision of the parietal peritoneum. During this procedure one must avoid opening into a bladder distended with urine or misplaced because of adhesions or tumors. This is accomplished by incising the peritoneum in the upper limits of the abdominal wound and looking through the peritoneum from the inner surface, the lowest limit of translucency in indicating the upper limit of the bladder. Preoperative catheterization should be a routine measure.

Downward displacement of the bladder in complete hysterectomy. In the downward displacement of the bladder effected to afford safe access to the uterine arteries, the lateral cervical attachments and the vagina, various precautions are necessary.

1 The vesicouterine fold of peritoneum may be divided too close to its reflection from the bladder. To eliminate this possibility the bladder is identified by a ridge in the lower part of the vesicouterine pouch and sufficient peritoneum for later peritonization preserved.

2 When dividing the fascial fibers between the bladder and the lower uterine segment and cervix one should displace the bladder downwards with gauze or fingers and cautiously snip with the points of the scissors directed toward the uterus.

3 Downward displacement of the bladder should be so gentle as not to damage muscle or vascular supply since it is conceivable that a vesicovaginal fistula could result from later distention of a weakened area.

4 The bladder if not sufficiently displaced off the anterior vaginal wall may be included in the incision intended to open into the anterior fornix.

5 The bladder may be caught in the clamps applied to the lateral cervical attachments. To prevent this one should displace the bladder downwards and outwards at each side and apply the clamps only under direct vision and touch.

6 In placing the angle sutures and in peritonizing accidental inclusion of a tiny piece of bladder wall is possible. Here again good vision is important.

Abdominal operations other than total hysterectomy. In hysterectomy or myomectomy for fibroids or chronic inflammatory disease the usual bladder relations may be disturbed. Care is necessary not only in preserving the bladder but the ureters also. In the course of a Wertheim hysterectomy both bladder and ureters must be constantly safeguarded especially in the area adjacent to the trigone. In extra-peritoneal fascial strap operations for stress incontinence the bladder neck is identified by its proximity

to the expanded end of a rubber malecot catheter. The author knows of 2 cases of incarceration of the distended bladder following intraperitoneal round ligament suspension. Both patients required celiotomy for relief. Such a method of uterine suspension is therefore not recommended.

INJURY TO THE BLADDER IN VAGINAL OPERATIONS

Various vaginal operations require elevation of the bladder along the supravaginal cervix and lower uterine segment.

In the Manchester operation for prolapse in which the lateral cervical ligaments are united anterior to the cervix, the bladder and ureters have occasionally been included in the approximating sutures.

In vaginal hysterectomy and in the interposition operation, in attempting to gain access to the vesicouterine fold of peritoneum the bladder lumen may be entered.

With Shaw's colporrhaphy difficulty may be encountered in suturing the cranial end of the post-urethral ligament on the front of the supravaginal cervix.

VESICO-VAGINAL FISTULA FOLLOWING TOTAL ABDOMINAL OR VAGINAL HYSTERECTOMY

The repair of such a fistula may be very difficult since the opening is in an almost inaccessible area without a cervix upon which to exert traction and facilitate exposure. The author believes it is important to wait 3 months before attempting repair to treat urinary infection with sulfonamide and ammonium chloride, and to use No. 000 plain catgut in the bladder and No. 0 chromic catgut in the vagina.

Clinical details of 9 cases of bladder injury following abdominal operations are presented.

W. RAY R. LANE, M.D.

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

Ectopic Pregnancy W D BEACHAM, CONRAD G COLLINS E, PERRY THOMAS and DAN W BEACHAM. *J Am M Ass.*, 1948, 136 365

The authors analyze a series of 1,059 cases of ectopic pregnancy collected from the records of the New Orleans Charity Hospital from 1906 through 1946. The racial incidence was compared in relation to the number of deliveries and number of gynecologic admissions. A summary of the graphs presented tends to show a slightly higher percentage of colored gynecologic patients with ectopic pregnancy than white patients 0.9 and 0.7 per cent, respectively. Comparison made with obstetrical admissions gives a white incidence of 1.5 per cent against a colored of 0.9 per cent. The difference is explained on the higher over all incidence of colored obstetrical admissions while the white admissions were confined largely to a group who had complications.

Age incidence figures showed that the majority of ectopic pregnancies in colored women occurred between the ages of 21 and 30 while in white women it was between the ages of 25 and 36.

An analysis of the authors' last group of patients from 1937 to 1946 comprising 381 showed that only 66 or about 17 per cent had not been pregnant previously. Thirteen or 3.4 per cent, had undergone a previously proved ectopic pregnancy.

Among 750 cases the right tube was involved in 60.1 per cent and the left in 39.9 per cent. 13.8 per cent of the pregnancies were intact, 70.8 per cent ruptured, and 16.4 per cent were classed as tubal abortions. Bilateral tubal pregnancy was seen in 3 patients and a combined extrauterine and intra uterine pregnancy was noted in 4 patients.

In the group of 381 patients seen between 1937 and 1946 there were 69 who had had previous lower abdominal surgery most often appendectomy. Salpingitis was reported in 134 or 36 per cent. No case of tuberculosis of the tube was noted.

The chief complaint was pain in 67.8 per cent, pain and bleeding in 20.3 per cent, and bleeding alone in 8.9 per cent. There was an accurate correlation of the location of the pain with the location of the ectopic pregnancy in 79 per cent. Shoulder pain occurred in 15.3 per cent.

The period of amenorrhea varied from none in 1.7 per cent to 7 months in 0.57 per cent, with the greatest peaks at 1 month (18.5%) and 3 months (14.3%). Colpocentesis was employed as a diagnostic step in 74 instances during the last 10 year period with positive findings in 69. The 5 other instances, reported as negative, were found to have free blood in the abdominal cavity at laparotomy a little later.

The operative procedures varied from unilateral salpingectomy to total hysterectomy with salpingectomy. The authors point out that the patient's

condition at the time of surgery should govern the extent of the procedure but that when the general condition warrants the "operator would do well to perform any indicated operation."

The maximum postoperative fever was noted in the majority of cases during the first 3 days, most often on the first day and in general it did not exceed a temperature of 101. The uncorrected mortality rate for the last 10 years was 2.89 per cent.

GEORGE B. BRADBURN M.D.

Transverse Presentation (Sobre presentación de tronco) MORIS VÁSQUEZ ZÚÑIGA. *Bol Soc chilena obst gín* 1947 12 236.

The author analyzes 158 cases of transverse presentation encountered among 30,038 admissions to the Angel C Sanhueza Maternity Santiago de Chile from April, 1941 to December 1946. The ages of the patients ranged from 15 to 48 years but 94 (59.4 per cent) were between 21 and 30 years of age. There were 130 multiparas (87.9 per cent) and 19 primiparas (12.1 per cent). The statistics of the various obstetrical services of the Capital seem to indicate that the number of transverse presentations has been decreasing in the last 10 years.

Among the maternal causes of transverse presentation multiparity was outstanding while bony pelvis dystocia and uterine malformation (uterus bicornis) were found in one case each.

Among the fetal causes, prematurity accounted for 48.7 per cent of the cases, macerated fetus for 10.6 per cent, and twin pregnancy for 15.1 per cent.

Among the ovular causes placenta previa was found in 6.3 per cent of the cases and hydramnios in 4.4 per cent.

Rupture of the membranes in the presence of a living fetus was spontaneous and premature in 12 cases with a fetal mortality of 5 (41.6 per cent) spontaneous and inopportune early in 26 cases with a fetal mortality of 6 (23.07 per cent) and spontaneous and timely in 20 with a fetal mortality of 5 (25 per cent). Rupture was artificial with complete dilatation in 29 cases, resulting in a fetal mortality of 4 (13.7 per cent) and with incomplete dilatation in 18 cases resulting in a fetal mortality of 3 (16.6 per cent).

Prolapse of an upper extremity was observed in 40 cases (25 per cent). In 3 of these there was edema and brachial paralysis of the prolapsed member which had regressed about 50 per cent at the time of discharge.

Prolapse of the cord occurred on 25 cases (15.6 per cent). Potential prolapse (procubitus) was observed in 5 cases. The fetal mortality for prolapse of the cord was 38 per cent.

Internal version was performed in 144 cases (90 per cent), in 21 of which the fetus was dead and in 123 the fetus was living. Preliminary manual dila-

tation of the cervix was necessary in 43 cases, and vulvovaginal dilatation was performed in 14 primiparae. Complications observed during or immediately after internal version included 12 perineal, 3 vaginal, and 11 cervical lacerations; elevation of the arms occurred in 21 cases; retention of the following head in 18; acute anemia in 3; obstetrical shock in 5; and rupture of the uterus in 3 (2.08 per cent). Simple puerperal endometritis was observed in 14 cases, grave puerperal sepsis in 3, and phlegmon of the right large ligament and infection of a vaginoperineal laceration in one each. Delivery by the natural route resulted in 27 fetal deaths (21.9 per cent) and 4 maternal deaths (2.75 per cent).

Segmental cesarean section was performed on 8 patients, in 6 of whom the fetus was living and in 2 dead. Laparotomy was performed on 2 patients to extract a dead fetus which was arrested and partly out of the uterus.

Transverse presentation has a bad prognosis for the fetus: 31 (19. per cent) fetuses being dead on admission. Delivery by the natural route resulted in a fetal mortality of 50 per cent in primiparae and 20 per cent in multiparae. There was no fetal mortality in extraction by the high route.

There are two prophylactic measures to be taken against the occurrence of transverse presentation: (1) strict control of the personnel of the domiciliary obstetrical services (any incompetent or negligent individual should be eliminated) and (2) any patient in whom a transverse presentation has been observed at 8 months or over should be hospitalized for labor even when the results of external version are satisfactory.

RICHARD KEMEL, M.D.

PUERPERIUM AND ITS COMPLICATIONS

The Diagnosis, Prevention, and Treatment of Puerperal Infection. ARTHUR M. HILL and HERBERT M. BUTLER. *Med J Australia*, 948, 27

The authors report their experience with puerperal sepsis at the Women's Hospital in Melbourne and also attempt to correlate the bacteriologic and clinical findings in 1,341 cases.

The bacteria associated with puerperal infections can be divided into three groups:

1. Anaerobic streptococci: the *Streptococcus hemolyticus* group A and the *Staphylococcus pyogenes*.
2. Hemolytic streptococci of groups other than A: *Bacterium coli*, nonsporing anaerobic bacilli, aerobic nonhemolytic streptococci, diphtheroids, and the *Clostridium welchii*.
3. The *Neisseria gonorrhoeae* and the *Streptococcus pneumoniae*.

The first group is by far the most important both from the standpoint of frequency of occurrence and severity of infections produced. In this series anaerobic streptococci were held primarily responsible for 80 per cent of the infections, although other bacteria were often present as well. Thirty of 53 patients with puerperal septicemia had blood cultures which were positive for the same organism.

Bacteria of the second group are less common and less virulent. Infections from bacteria of the third group are very rare.

On the basis of source, the bacteria responsible for puerperal sepsis fall into three categories: those from without (mainly the *Streptococcus haemolyticus* group A and the *Staphylococcus pyogenes*) those which are normally inhabitants of the vagina (hemolytic streptococci of groups other than A, anaerobic streptococci, anaerobic gram-negative bacilli, diphtheroids, and aerobic nonhemolytic streptococci) and those which come from viscera adjacent to the bladder (anaerobic streptococci from the urethra and the *Bacterium coli* and *Clostridium welchii* from the rectum).

Puerperal infections are also divisible into the infectious and the non-infectious on the basis of the ability of the causative bacteria to spread from case to case. The *Streptococcus hemolyticus* group A is transmitted by dust and droplet, while the *Staphylococcus pyogenes* infections are usually transmitted by contact. Mechanical introduction is most common with the fecal bacteria (*Bacterium coli* and *Clostridium welchii*). The anaerobic infections are not infectious.

The severity of the disease depends on the virulence of the strain, the degree of maternal resistance, and the associated bacteria. Anatomically puerperal infection occurs in the following grades of severity: (1) infection localized to the birth canal—this is both the mildest and commonest form; the most frequent manifestation being acute endometritis; (2) infection spreading beyond the birth canal but localized to the pelvis—this is exemplified by pelvic peritonitis, pelvic cellulitis, and pelvic thrombophlebitis; (3) general peritonitis; and (4) septicemia. The latter two are grave varieties of sepsis. On the whole, however, the authors find only slight correlation between the clinical picture and the etiologic bacteriologic agent.

Whenever the course of the puerperium is complicated by (1) a temperature of 100° F or higher, (2) a temperature of 100° F or more for 24 hours, (3) jaundice, (4) unexplained tachycardia, or (5) an offensive or purulent discharge, a careful history and a complete physical examination are in order. Vaginal and urinary cultures and in some instances blood cultures, should be taken.

Preventive measures in puerperal infection are of two types—those employed by the community and those applied in the individual case by the obstetrician and others in attendance. Communal measures include efficient prenatal clinics and lying-in units available to all patients. The obstetrician on the other hand, must bring his patient to the best possible state of health, and conduct the labor and puerperium with a minimum of interference and a maximum of aseptic technique. Prophylactic chemotherapy and isolation are essential at times.

Good nursing care is the keystone of treatment. Advantages are a liberal diet, maintenance of fluid balance, Fowler's position, bland aperients, ferrous

iron and blood transfusions. Chemotherapeutic agents and antibiotics are almost routine. Surgical measures must at times be employed.

Although puerperal infection is not so severe or frequent today as 15 years ago, the precise application of modern knowledge and methods of control should relegate this condition to a minor role in the production of maternal morbidity and mortality.

WARREN R. LANG, M.D.

Penicillin and Sulfonamide Therapy in Puerperal Infections (Penicilloterapia y sulfamidoterapia en infecciones puerperales) HERNAN MORA LORCA and ORLANDO TRIVELLI ROCCHI. *Bol Soc chilena obst ginec.*, 1947 12 189.

A study of the files of the Angel C. Sanhueza Maternity, Santiago de Chile for the 4 year period from 1943 to 1946 shows that 742 cases of puerperal infection were treated with sulfonamides and 206 with penicillin. The mortality in the sulfonamide treated cases was 0.94 per cent for puerperal infections in general, 50 per cent for puerperal sepsis and 0.86 per cent for pelvic processes. The mortality in penicillin treated cases was 5.82 per cent for puerperal infections in general, 38.46 per cent for puerperal sepsis and 1.66 per cent for pelvic processes.

The average number of days required for the acute symptoms to become chronic (effectivity time) in the sulfonamide and the penicillin treated cases respectively was 7.15 and 10.33 for puerperal infections in general, 6.25 and 3.6 for putrid endometritis, 6 and 5.35 for endometritis in general, 4.8 and 4.7 for simple endometritis, and 7.99 and 9.6 for purulent endometritis.

Consequently the mortality is lower with penicillin therapy in puerperal sepsis, but this result is not significant statistically. The mortality is lower with sulfonamide therapy in puerperal infections in general and in pelvic processes, but the result is significant only in the first group. As to the effectivity time, penicillin has a better average in endometritis in general, simple endometritis, and putrid endometritis, but the result is significant only in the last group. The sulfonamides have a lower average of effectivity time in puerperal infections in general and in purulent endometritis, but the result is significant only in the first group. Penicillin therapy with associated treatment shows only one-third of the mortality of penicillin therapy alone, but this result is not significant.

The reason why penicillin has been less efficacious could lie in (a) the presence of penicillin resistant germs, (b) exaggerated confidence in its action, with disregard of other treatments, and (c) in many cases lack of exact knowledge concerning the use of penicillin. In addition the power of the drug may vary in connection with many factors such as transportation, changes of climate, and packaging. If the lower action of penicillin in many cases is due to the presence of penicillin resistant germs the indication would be to make an early and careful bacteriologic investigation in every puerperal infection to serve as

a guide in the choice of the drug to be used. With this precaution a decrease or a reversal in the percentages should be obtained in a few years. When there is no chance to identify the causal germs it would be advisable to institute a combined treatment with penicillin and sulfonamides. Together with the antibiotics other therapeutic measures should not be delayed or ignored.

RICHARD KEMEL, M.D.

Meningitis and the Puerperal State; Tuberculous Meningitis (Meningite e stato puerperale: la meningite tubercolare) GIOVANNI LUCCHETTI. *Riv ostet ginec.* 1947 2 164.

The author reports 3 personal cases of tuberculous meningitis associated with pregnancy which he encountered in the past decade and reviews the 46 cases which he found in the literature.

The primary localization of the tuberculous infection which must necessarily exist in any case of tuberculous meningitis was clinically silent in over 50 per cent of the cases. The meningitis occurred predominantly in young women during their first pregnancy and appeared in the third trimester of the pregnancy in more than half of them. Lucchetti's patients were 26, 22 and 23 years old, respectively. In 25 per cent of the cases the meningitis appeared suddenly in the immediate postpartum period and this suggests that labor is a revealing or aggravating factor of the morbid process. The reason for the predilection of the meningitis to appear during these two periods is supposed to lie in the so-called anergy of pregnancy and the presumed massive introduction into the circulation of tubercle bacilli expressed from the site of placental insertion (tuberculous placentitis).

Pregnancy may lend a particular aspect to tuberculous meningitis, especially by exaggeration of some symptoms such as vomiting and convulsions. As a result diagnostic errors are frequent, especially with grave vomiting in the first half and eclampsia in the second half of pregnancy. Even the cerebrospinal fluid presents unusual characteristics, probably because the changes due to the meningeal infection interfere with those due to pregnancy.

For the differential diagnosis it is useful always to keep in mind the possibility of this rare entity and never to omit exact evaluation of all the clinical and diagnostic elements in doubtful cases, especially the anamnesis, the urine, spinal fluid and ocular fundus examinations, the arterial pressure, the time of appearance of disturbances common to pregnancy which differs from that in the ordinary case such as vomiting in the second half and convulsions in the first half.

Tuberculous meningitis rarely causes untimely interruption of pregnancy (12 per cent of the cases). Usually the patient dies during pregnancy if there is no intervention. Spontaneous as well as induced labor proceeds slowly because of marked uterine hypokinesia.

Pregnancy rarely modifies the course of the meningitis, but labor has a deleterious action on the dis-

case provoking it or aggravating its symptoms or rapidly leading the patient to death. In tuberculous meningitis, much more than in other tuberculous localizations during pregnancy the fetus is seriously compromised, probably through the mechanism of transplacental infection. Over 50 per cent of the fetuses in spontaneous or artificially induced labor die in the uterus or at the beginning of extrauterine life.

The treatment must consider especially the interests of the child. If the fetus is living intervention is indicated as soon as the diagnosis is made. If delivery can be obtained easily by the natural route, premature labor is induced otherwise, cesarean section is performed. Induced premature labor may eventually be accelerated, but this exposes the fetus to grave dangers because it is already weak. For cesarean section the most rapid type should be selected.

RICHARD KEMEL, M.D.

NEWBORN

Some Causes of Death of Stillborn and Newborn Infants Based on Postmortem Findings (Alcune cause di natimortalità sulla base dei reperti topici) CONRADO BELVEDERE. *Riv. Ital. ginec.*, 1947, 30: 209.

Of 10,727 newborn infants delivered in the Obstetrical Clinic of Bologna during the period from 1935 to 1944, 993 (5.05%) died or were born dead.

The dead infants may be divided into 3 groups: (1) those who died before labor prematurely or at the termination of pregnancy; (2) those who died during the delivery; and (3) those who lost their lives during the first 7 days after the delivery.

The author tabulated 127 stillbirths and deaths of newborn not according to the topography of the fatal lesion but in correlation with the etiology and clinical findings.

In the first group of 46 cases, the fetal death was attributable to intruterine asphyxia provoked by a variety of factors. In the great majority of cases punctiform cerebral or meningeal hemorrhages were found.

In the second group of 22 premature deaths, the fatality was caused by a congenital debility without evidence of definite organic alterations.

In a group of 17 cases, acute pulmonary conditions, chiefly bronchopneumonitis, were responsible for death.

In 10 instances congenital fetal cardiopathies chiefly a patent foramen ovale or a persistent ductus Botalli were present.

In 12 cases endocranial hemorrhages of apparently nontraumatic origin and in 4 cases similar hemorrhages of traumatic origin were considered to be the cause of death.

A group of 16 cases the anatomopathologic findings did not fit into a single picture.

In the first mentioned group of 46 cases had podalic presentations. In 3 infants centa previa, and in 2 premature detach-

normally inserted placenta was found to be responsible for the asphyxia of the fetus. In 2 cases, a spontaneous prolapse of the umbilical cord, and in 3 a prolapse following the application of forceps, was recorded.

The last group consisted of a variety of conditions, such as congenital malformations of the urinary apparatus incompatible with life e.g., aplasia of the kidneys, obliteration of the ureters, and hypertrophy of the thymus gland with compression of the superior vena cava.

MISCELLANEOUS

The Permeability of the Human Placenta to Sodium in Normal and Abnormal Pregnancies and the Supply of Sodium to the Human Fetus as Determined with Radioactive Sodium. L. B. FLECKNER, D. B. COWIE, L. M. HELLMAN, W. S. WILDE, and G. J. VOISARD. *Am. J. Obst.* 1948, 55: 469.

The present article is concerned primarily with the following problems: (1) measurement of the permeability of the normal human placenta to sodium from early in gestation to term; (2) comparison of the permeability of the human placenta with that of other placentas of the hemochorial group; (3) measurement of the effects of disease on placental permeability; and (4) evaluation of the supply of sodium to the fetus as this is related to the requirement for sodium during fetal growth.

The rationale and methods used to measure sodium transfer in terms of a radioactive isotope are presented in detail.

The human placenta, as is true for all the placental types which have been studied with the tracer technique, undergoes a very considerable increase in permeability to sodium as gestation proceeds. The peak in transfer rate per unit weight of placenta occurs at about the thirty-sixth week when it is approximately 70 times as great as at the ninth week, the earliest in the authors' series, and is followed by a rapid decline in permeability to term. These changes can be correlated with morphological changes which occur in the placenta during the process of aging.

fore reliable conclusions about placental function can be drawn.

The use of tracer substances permits the study of that aspect of fetal nutrition which is concerned with the quality of substances supplied to the fetus as this is related to the growth requirements of the fetus. The fetus receives across the placenta at the twelfth week of pregnancy 160 times as much sodium and at the fortieth week 1100 times as much as is incorporated in the growing tissues. This is the single exception which has been found to the hypothesis that the fundamental principle underlying placental function is that the rate at which substances are transferred to a unit weight of fetus shall parallel the relative growth rate of the fetus.

JOHN R. WOLFE M.D.

Report of a Survey of Children Born in 1941 with Reference to Congenital Abnormalities Arising from Maternal Rubella. P. R. PATRICK. *Med J Australia* 1948 1 431

The author reports the results of a survey of children born in 1941 in Queensland, Australia, with reference to congenital abnormalities arising from maternal rubella. A questionnaire was sent to 9,674 women who gave birth to infants in 1941. Of these 7,822 were returned completed. The following questions were asked in the letter sent to these women:

1. Did you suffer from German measles in 1940?
2. If so, were you pregnant at the date of the attack of German measles?
3. If you were pregnant, how many months were you pregnant at the date of the attack?
4. Has your child shown any physical defects—especially those mentioned in the beginning of my letter?

A description of the symptoms of German measles was included in the letter as follows: "Pale pink rash clustered in small groups first on the face and neck and extending to the trunk and the limbs. On the second day the face is completely covered by rash. Sometimes there is no fever at all. There is a tender swelling of the glands behind the ear and back of the neck. They may reach the size of small peas. The glands in the armpit and groin frequently enlarged."

There were 268 cases in which mothers were certain they had rubella during that particular pregnancy. Of these 134 were in the Brisbane area, and 139 were examined clinically. These cases are tabulated and form the basis for the present report.

Of the 139 children examined 51 had some abnormality. Of these 37 had a serious defect. These included deaf mutism, mental deficiency, congenital cardiac disease, and cataracts. Thirty-seven patients had hearing defects, the vast majority (27) being grade 3 deafness (deaf mutism).

Of 40 children born in 1941 and (at the time of survey) attending the School for the Deaf and Blind 26 gave a history of maternal rubella.

Evidence was also gathered which showed that some mothers suffered miscarriages and some had

had stillborn infants after having suffered from rubella in pregnancy. The rubella may or may not have been the cause.

In Brisbane 28 children (of 77 cases) whose mothers had rubella in the first 4 months of pregnancy had serious abnormalities and 11 more had minor abnormalities.

No relationship was noted between the period of pregnancy during which the mother had rubella, and the type of abnormality. The most frequent abnormality was deafness, then in order of frequency congenital heart disease, mental deficiency, and cataracts.

Examination of the teeth of the children with the history of maternal rubella revealed the following abnormalities that might have been influenced by the rubella: (1) congenital absence of isolated deciduous teeth, (2) hypoplasia, and (3) retardation in tooth eruption.

The author makes the following suggestions: (1) rubella might be added to the list of notifiable diseases, (2) deliberate exposure of all girls to the disease might be practiced, (3) inoculation with rubella might be developed, suitable techniques are not yet available, (4) exposed pregnant women might be treated with immune globulin, (5) pregnancy might be terminated if rubella had been contracted in the first 4 months—a certain method but its justification is debatable, and (6) warn pregnant women not to expose themselves to the disease.

HARRY FIELD, M.D.

A Study of Maternal Deaths in the Philippine General Hospital. ALFREDO BARRA. *J. Philippines M A* 1948, 24 75.

From April 1, 1945 to July 31, 1947 there were admitted to the maternity service of the Philippine General Hospital 6,676 patients; the results were 4,611 live births and 212 stillbirths. There were 70 maternal deaths. Based on the total number of pregnancies the rate of mortality was 1.04 per cent. Based on the number of live births the ratio was 15.1 per 1,000 live births. At the Chicago Lying In Hospital the maternal death rate based on the number of pregnancies was 0.17 per cent for the period from 1931 to 1945. At The New York Lying In Hospital the figure for 11 years based also on the number of pregnancies was 0.19 per cent (uncorrected).

Of the 70 maternal deaths 34 (48.57%) were due to hemorrhage, and 22 (31.43%) were due to toxemia of pregnancy. In the hemorrhage group 11 (15.71%) were due to rupture of the uterus and in the toxemia group 18 (25.71%) were due to eclampsia. These were the major causes of 56 of the 70 maternal deaths. The causes of the remaining deaths are listed as follows: placenta previa (5), postpartum hemorrhage (5), hydatidiform mole (4), retention of placenta, manual extraction and shock (3), tubal pregnancy, salpingectomy and peritonitis (2), ablatio placenta (2), rupture of abdominal aneurysm (1), acute anemia after symphysectomy (1), acute

yellow atrophy of the liver (1) nephritis and pregnancy (3) puerperal infection peritonitis or both (1) pyelonephritis 1 case with acute transverse myelitis (3) bronchopneumonia (2) obstetrical shock (3) impending rupture of the uterus—Porro section, and shock (1) intra-abdominal pregnancy—partial hysterectomy (1) cardiac failure—valvular disease (1) intestinal obstruction (1) and military tuberculosis, sepsis, and miscarriage (1)

A very interesting observation concerning the list of causes is the very low incidence of infection as a cause of death, especially puerperal infection. At the Chicago Lying In Hospital from 1931 to 1935 infection accounted for 39.50 per cent of the deaths and at New York Lying In Hospital from 1933 to 1935 infection accounted for 22.80 per cent of the maternal deaths.

In this report hemorrhages claim the heaviest toll. Of the various hemorrhages rupture of the uterus was the most common cause. Two cases of rupture were due to the injudicious use of pituitrin one of the patients had 3 consecutive injections of $\frac{1}{2}$ c.c. each. Two ruptures were associated with cran-

iotomies. One of the fetuses was a double headed monster.

Only one patient in this whole series was given the benefit of blood transfusion. Up to this date the Philippine General Hospital has not acquired the proper facilities for blood transfusion. Five cases of death accompanied placenta previa. In all of these there were no available donors. Five cases of death were due to severe postpartum hemorrhage. Four patients had been admitted in extremis.

The general impression given by these figures is that most of these deaths are preventable. However, a long range program of education of the laity, the training of more specialists in obstetrics and the establishment of more maternity services to meet modern requirements would be required.

The figure for mortality from rupture of the uterus alone (15.71%) indicates that patients are getting poor and inadequate prenatal care. The high incidence of eclampsia also bears this out. The greatest need for more adequate patient care in the hospital seems to be better transfusion facilities.

HARRY FIELD, M.D.

GENITOURINARY SURGERY

ADRENAL, KIDNEY AND URETER

Two Cases of Disease of the Vascular System Treated by Bilateral Suprarenal Medullectomy
DAVID H. BYCOLD *Acta chir scand* 1948 96 317

Bggjeld reports the cases of 2 patients with peripheral vasoconstrictive disease in which sympathetic ganglionectomy did not sufficiently relieve the symptoms and in whom bilateral suprarenal medullectomy produced favorable results.

The first patient was a 58 year old male who had lost substantial parts of his fingers and toes because of peripheral vascular disease and in whom partial improvement had resulted from resection of the second third and fourth lumbar sympathetic trunk ganglia and the stellate ganglia. The left leg was amputated after a recurrence and bilateral suprarenal medullectomy was then performed. All pain edema, and loss of substance stopped.

The second patient was an 18 year old woman with cyanosis, edema, and trophic changes in both lower extremities. Bilateral lumbar ganglionectomy was performed. Two years later because of recurrence in the hands as well as in the knees bilateral medullectomy was performed in two stages. An excellent cure was obtained. The author exposed the suprarenal gland with an oblique incision under the twelfth rib. The latter is mobilized by resecting 1 cm of the bone close to the transverse process. The adrenal gland is exposed and incised, and the medulla is curetted until the gland is transformed into a cavity.

The author has not however had sufficient experience with this operation in arterial hypertension to draw any conclusions. DAVID ROSENBLUM, M.D.

A Case of Suprarenal Pheochromocytoma Clinically Diagnosed and Cured by Operation
NILS ALWALL and H. B. WULF *Acta chir scand*, 1948, 96 337

Alwall and Wulf report a case of a 43 year old man who was observed for 4 years because of attacks of vomiting, heartburn, pallor, palpitation, trembling, fatigue, sweating, and headache. These attacks lasted from 2 to 10 minutes and occurred as frequently as five times a day.

Plain abdominal films demonstrated a rounded well-defined shadow above the right kidney. The blood pressure was normal on repeated examinations. A diabetic type of sugar tolerance was shown by tests. Pressure on the site of the tumor, hyper-ventilation, and exercise did not produce an attack or hypertension.

The tumor was removed through a right renal incision. The operation was uneventful and recovery was normal. The pathologist reported the tumor as a pheochromocytoma.

The authors urge that pnelography, planography, perirenal insufflation and biochemical studies should

be employed in the diagnosis of suprarenal pheochromocytomas
DAVID ROSENBLUM, M.D.

Metastasizing Hypernephroma and Adenoma of the Adrenal Gland
JOHN A. TAYLOR *J Urol*, Balt. 1948 59 557

The author reported an interesting case of association of bilateral massive adrenal adenoma and hypernephroma (clear-celled carcinoma) of the right kidney with extensive metastases. Less than 70 such cases have been recorded in the literature. In practically all cases including the one under discussion these tumors were encountered at autopsy.

ROBERT TURELLI, M.D.

Radiologic Diagnosis. Perirenal Artificial Emphysema. Original Technique (Diagnóstico radiológico. El neumorrén. Técnica original) M. RUIZ RIVERA *Arch. españ. urol* 1948 4 225.

The author now modifies the technique for inducing artificial oxygen gas emphysema about the kidneys and other organs of the posterior abdominal wall which he originally published in the *Revista Clínica Española* (May 15 1947).

With the present technique the spinal puncture needle is introduced into the presacral space at the level of the sacrococcygeal joint, about 1 cm from the midline on either side. Preferably the patient maintains the genupectoral decubitus position the needle being passed inward toward the midline, upward toward the head and somewhat anteriorly in order to reach the presacral retroperitoneal tissues close to the anterior surface of the sacrum and in the midline. After the usual precautions for such injections have been taken the amount of oxygen estimated to be sufficient is introduced into the presacral fatty tissues and guided to the parts of the retroperitoneal tissues to be examined by manipulation of the patient's body posture perhaps the entire process being controlled at intervals by the fluoroscope.

The advantages claimed by the author for the present method over the preceding one are the avoiding of the menace of air embolism (by the present method the most highly vascular tissue traversed is the skin) and more even diffusion of the gas so that even in the presence of transposed or atopic organs the examination is not hindered. As a further advantage of the method might be mentioned the tendency of the injected gas to remain below the level of the diaphragm. Not only does one obtain excellent images of the kidney and the psoas muscle by this method but also of the suprarenals spleen liver the slips of insertion of the diaphragm and at times also of the gall bladder the thickness of the abdominal walls and of many other details which cannot be identified at the present time such as nerve ganglia, groups of lymphatic glands and neurovascular bundles.

The technique is simple and rapid and as a rule, will succeed at the first try.

JOHN W. BRIDGMAN, M.D.

Bismjol" as a Contrast Medium for Ascending Pyelography (L'uso del bismjol come mezzo di contrasto nella pielografia ascendente) PAOLO ZOBOLI and ENRIKETTO REGGIANI. *Boll. Soc. med. chir. Modena*, 1947 47 77

Sodium bromide occasionally forms a small bolus in the ureters or the renal pelvis which may predispose to the formation of a calculus. Furthermore, the substance cannot be sterilized by heat without losing some of its opacity. Sodium iodide may have an irritating effect on the vesical mucosa or that of the renal pelvis. Lipiodol has no irritating effect and produces good shadows, but because of its great viscosity it is eliminated very slowly.

Because of such disadvantages of the opaque media used for ascending pyelography the authors attempted to replace them by a new compound called "bismjol." The composition of this new radiopaque substance is as follows: sodium iodobismuthite (0.15 gm.), sodium iodide (0.24 gm.) and ethylene glycol (30 c.c.). The compound was employed in 23 patients and it proved to produce good shadows. The substance is not toxic and has none of the aforementioned drawbacks of the customary radiopaque media.

Apparently there are no contraindications to the use of bismjol, except the conditions in which pyelography as such is not advisable, e.g. tuberculosis, and grave heart disease. Nausea, chills, vomiting or any other toxic symptoms have not been observed following its use.

Bismjol not only is aseptic but it displays also an antiseptic effect, and therefore the number of white blood corpuscles in the urinary sediment is usually diminished after pyelography. The substance has a low viscosity and is therefore easily eliminated with the urine. No irritating effect on the mucosa of the ureters or the renal pelvis has been observed. On the average from 5 to 7 c.c. of the solution are introduced on each side and the injection is stopped immediately when the patient begins complaining of pain. When the examination is finished, a small amount of normal saline solution is injected through each catheter.

JOSEPH K. NARAY, M.D.

Surgical Treatment of Nephritis. MANUEL E. PERAZURRA and EDUARDO HERNANDEZ I. *J. Urol. Balt.*, 1948, 59: 484.

The nephritis concept was vague and indefinite in former times and it remains so in our day. In spite of the excellent descriptions of highly qualified researchers

it is actually known that one of the most important causes of renal insufficiency in glomerulonephritis is renal ischemia, which is produced by the obstruction of small arterioles mainly in the glomeruli. The adequacy of any treatment is to build up an increase of intrarenal blood flow which thus far has never

been accomplished by any medication, probably because of the autonomic character of the renal circulation.

Recent studies of Homer Smith show that a new formation of vessels which supply the tubuli can be seen in diseased kidneys. Therefore, even if the glomerular filtration is not improved an advance in the process of secretion and reabsorption takes place in the tubules forming an important part of the total renal function. We can thus believe that an organic reaction takes place which relieves renal ischemia by the development of new vessels. Hence the use of any procedure which favors this reaction is completely justifiable.

This new vascularization has been frequently demonstrated in operative kidneys microscopic slides or by color injections of the aorta with ligation of the renal arteries. Godard, Claude and Balazard, and Gentil and others, including the authors have been able to prove this. They think that these facts justify the surgical treatment of nephritis.

The authors do not advise that surgical treatment be carried out in all early cases of nephritis but believe that it should be used whenever obvious failure of the usual medical treatment is observed without waiting until the lesions become nonreversible.

Before the surgical treatment is undertaken the following routine should be carried out: (1) investigation and treatment of all infectious foci in the teeth, tonsils, appendix, and prostate (there usually is more than one focus to be found, and in this country the highest percentage was found in the group of dental foci) (2) correct diet and sufficient vitamin supply (especially vitamin C) (3) complete rest and (4) sulfa drug or penicillin treatments as indicated.

If in spite of this routine and close supervision over a certain time, we find a persistence of the symptoms or if the outlook is more serious, surgery should be considered. The cases are classified according to the following features, which are the indications and contraindications for surgical treatment: (1) cases with clinical evolution of from 4 months to 1 year; (2) with blood pressure not higher than 180 mm. (3) with no lesions of the retina; (4) with blood urea not higher than 60 mgm. per 100 c.c. of blood; (5) with blood creatinine not higher than 4 mgm. per 100 c.c. of blood; (6) with an Ehrlich xantoproteic reaction of less than 60 units; (7) with phenolsulfophthalein excretion of more than 35 per cent in 4 hours; and (8) with a urinary specific gravity higher than 1.015 after a dry diet given during 18 hours.

There is a common acceptance of the idea that the circulation of the kidney is completely autonomous and that the section or destruction of the renal nerves does not modify it in any way. However one must consider the association between the small arterial vessels of the kidney and the nervous system a fact that can be verified by the study of emotional reactions and arteriospasm. We also know that epinephrine produces enlargement of the kidney because of a spasmodic condition of the efferent vessel of the glomerulus. In view of the possibility

of avoiding the vasoconstriction produced by epinephrin the authors combined the nephro-omectomy with denervation according to Papin's technique. On the basis of these statements the authors have carried out the following technique in all of their cases:

1. Pfannenstiel's incision with resection of the last rib. In this way there is a wide operative field and trauma to the kidney which would be caused by a long operation carried out under other conditions is avoided.

2. Denervation according to Papin's technique.

3. Opening of the peritoneum and withdrawal of a portion of the omentum. This is fastened to the peritoneal opening by means of separate stitches in order to avoid retraction.

4. The omentum is placed between the renal tissue and the renal capsule by means of three clusions on the latter. One is made on the anterior face, the second is made on the external edge and the third on the posterior face following the procedure reported by Ritter.

5. Drainage and suture.

In order to gauge the results obtained by this treatment the clinical symptoms and the results of the laboratory tests must be considered. The first to consider is the presence of edema, lumbar pain, blood pressure, and microscopic hematuria. Later the following are closely watched: (1) urinary output, (2) urinary specific gravity, (3) albuminuria, (4) microscopic hematuria, (5) urinary casts, (6) blood urea, and (7) phenolsulfonphthalein excretion.

In order to have a more exact concept of hematuria and the existence of casts some of our cases were given the Addis count which was considered an important factor relating to this subject.

The authors are well satisfied with the results obtained from the operation. Most of the symptoms and the hematuria, casts, and albumin disappeared soon after the operation in many of their cases.

Of 11 patients who were operated upon 2 died. A study of these cases led in part to the establishment of the limits for the indications for surgery as neither of the 2 patients who died was within these limits. One of the two had severe hypertension with lesions of the retina; the other had advanced renal insufficiency.

JOHN A. LOEY M.D.

Diagnostic Considerations and Therapeutic Management of Renal Anthrax. (Consideraciones diagnósticas y conducta terapéutica en el antrax del riñón). ADOLFO FOXE. *As. ciruj. Rosario*, 1947 15 196.

This article reports 5 cases of renal anthrax. The diagnosis was made on physical findings, and confirmed by x-ray and urologic studies. Two of the 5 patients were treated with 50,000 units of penicillin given intramuscularly every 3 hours and recovered without incident.

The 3 others had persistent elevation of temperature despite the fact that they received 100,000 units of penicillin every 3 hours. They were subjected to nephrectomy and recovered. The typical necrotic

areas with abscess formation were readily demonstrated in the operative specimens.

STEPHEN A. ZIEGLER M.D.

Solitary Cyst of the Kidney: Case Report. R. ABBEY SMITH. *Brit. J. Urol.* 1948 20: 8.

The author discusses the literature on solitary cyst of the kidney and reports a case in a boy 18 years of age, with the following history:

Three years previously he had fallen 10 feet, following which he had severe sharp pain beneath the left ribs in the midaxillary line. After several days of bed rest the pain subsided completely. However on several subsequent occasions of physical strain he had recurrences. On one occasion he passed dark urine which he thought might have been blood.

Physical examination revealed a mass in the left hypochondrium and lumbar region. An intravenous and retrograde pyelogram showed obliteration of the upper and middle calices of the left kidney.

On operation a normal sized spleen was found to be pushed downward and forward by a large cyst continuous with the lower pole of the kidney. A left transperitoneal oephrectomy was performed.

The specimen measured 10 by 5 by 4 inches and weighed 3 lbs. 8 ozs. The large unilocular cyst of the lower pole contained 100 c.c. of clear yellow fluid.

JOHN A. LOEY M.D.

Prognosis in Polycystic Kidney Disease. THOMAS R. ALMOND. *Conn. J. Urol. Balt.* 1948 59 477.

The lot of the patient with polycystic disease must have been improved materially with the introduction of the superior chemotherapeutic and antibiotic agents of this period. It is true that renal infection will develop in 50 per cent of these cases and that it will be severe in 30 per cent. This incidence of infection will undoubtedly continue but its control is much more certain. Therefore the need for surgical intervention of which drainage of renal and perirenal abscesses was most frequent should arise less often. Similarly with better control of infection stone formation, which heretofore has occurred in 50 per cent of these patients, might be reduced. Gross hematuria will probably continue to appear in from 30 to 40 per cent of these patients. Forty years of age should continue to be the average age at onset of the symptoms. Nor is there any known factor at present which is likely to reduce hypertension in these patients from its present high incidence of 60 per cent.

Surgery other than of the urinary tract in persons with polycystic kidneys is usually safely tolerated provided renal function is still practically normal. The enthusiasm for Rovsing's operation seems for the most part only lukewarm. It was followed too often by hemorrhage and infection. Penicillin, streptomycin and the sulfonamides may well increase the safety of the operation and permit its proper evaluation when separated from these former by too frequent sequelae.

Fairly long survival after diagnosis was reported in from 55 to 65 per cent of the cases, i.e. for from 5 to

25 years and 15 per cent for from 2 to 4 years. 30 per cent of the patients died within 2 years of the onset of symptoms. In Sieber's series of 244 collected cases quoted by Doolin only 18 patients survived the sixtieth year.

In general the patient in whom polycystic disease is diagnosed in the third or fourth decade can expect a much shorter life than the patient in whom the diagnosis is not made until the fifth or sixth decade. This is evidently because cysts grow more rapidly (with symptoms) in the younger individual and, therefore the approach toward renal failure is more rapid. In approximately 50 per cent of the cases of polycystic disease coming to autopsy uremia is said to be the lethal factor. Although it has not yet been possible to study statistically an adequate series of cases since the antibiotics became available in 1945, it is safe to predict that such a study will show less frequent need for surgery, less frequent death from uncontrollable infection and modest prolongation of life through reduced parenchymal damage by infection.

JOSEPH A. LACEY, M.D.

The Importance of Accurate Pathologic Classification in the Prognosis of Renal Tumors. N. CHANDLER FOOT and GUSTAVUS A. HONCHER, *Surgery* 94:8 3, 369.

The authors stated that there is a histogenetic, pathologic, and clinical justification for classifying renal tumors into (1) those of mesodermal origin and (2) those of ectodermal origin, and that the tumors of the former category have a better prognosis than those of the second category. The tumors derived from the mesoderm are simple adenomas and renal-celled carcinomas (hypernephroma or clear-celled carcinoma) including some tubular forms. The tumors derived from the ectoderm are transitional-celled papillomas, transitional-celled carcinomas, epidermoid carcinomas, and some carcinomas of the collecting tubules. (The tumors derived from embryonal tissue are juvenile and adult embryonal carcinomas and mixed embryonal tumors including those of Wilms.)

In a series of 66 renal tumors the renal-celled type of carcinoma outnumbered the other forms 2 to 1. The prognosis of this type of renal carcinoma may be based with a reasonable degree of accuracy upon the microscopic appearance of the tumor. Patients with well-differentiated tumors have a good chance of living 5 or more years. The ectodermal neoplasms and those developing in mixed mesenchymal nests give an almost hopeless prognosis.

ROBERT TURNELL, M.D.

Mixed Tumor of the Kidney. NORMAN J. HICKEL and GEORGE D. PRINCE, *J. Urol.* Balt., 94:3, 59; 572.

The authors reported a rare case of lipomyoma of the left kidney without gross or microscopic hematuria. The greater differentiation of this mixed tumor separates it from Wilms' adenoma and accounts for a better prognosis.

ROBERT TURNELL, M.D.

Cancer and Tuberculosis in the Kidney (Cáncer y tuberculosis en el riñón). A. PUIGVET and A. ORTIZ AMORRILA, *Arch. ciruj. med.* 94:3, 4, 300.

Two patients are reported in whom there were a cancer and a tuberculous process associated in the same organ. The authors merely add these case histories to the other 17 so far published without attempting to explain the possibility of an intimate coexistence of the strongly aerobic tuberculous process with the strictly anaerobic cancerous process, a possibility which has been emphatically denied in the past.

The first case was that of a 45 year old male with a long history of pulmonary, epididymal, and urinary tract symptoms suggesting tuberculosis. Hematuria, fever and asthenia had been present off and on for 4 or 5 years. The excised kidney was found to be enlarged, normal in shape but with a huge mass, as large as the kidney itself, riding in hood like fashion on its upper pole. This mass was made up of typical tuberculous tissue but was without trace of other tissue which might give a hint as to the organ from which it took origin. Also scattered in the kidney tissues were small centers exhibiting tuberculous changes. In the middle calyx of the opened kidney pelvis a large tumor mass filling the entire renal pelvis was implanted by means of a sturdy pedicle. In two other locations within the kidney tissue were found small nodules of neoplastic infiltration having the same general histological characteristics as the original mass. This mass on histological examination was found to consist of fine connective tissue strands covered by a single layer of cubical epithelial cells with acidophilic protoplasm. The nuclei were large, spherical or oval in shape, with one or two nucleoli and finely granular chromatin. The diagnosis was papillary epithelioma. However in many areas, the cells were irregularly arranged, tending to multiply by direct division (no mitotic figures) in a straight line so as to form strandlike and tubelike figures.

The second case was that of a 44 year old male complaining of frequent urination and turbid purulent urine. The prostate, bladder walls and peritoneal mucosa on the right side exhibited typical durations and ulcerations of tuberculosis. The urine contained tubercle bacilli. The right kidney was enlarged and smoothly globular and descending pyelography presented the appearance of a huge rounded mass pushing the pelvis and calices medially and stretching them vertically. The mass was diagnosed as tuberculosis of the right kidney with excision of the lower pole. Upon nephrectomy however it was found that the mass in the lower pole consisted of a cystic degeneration of a Grawitz tumor (hypernephroma). The middle zone of the kidney contained numerous areas with typical tuberculous changes. There were cavitations, caseation, and collections of epithelial and Langhans type of giant cells. One of these tuberculous cavitations bordered directly on one of the epitheliomatous cystic locules, so that between the two there was only a narrow connective tissue septum made up of edematous connective tis-

soe stroma with inflammatory infiltration, and a few muscle fibers corresponding to the muscular strands of the intrapylar smooth muscle sphincter all to evident process of hyaline degeneration. In the part corresponding to the tuberculous cavitation there were caseous changes and epithelioid and round-cell infiltrations, while on the opposite side of the septum was the cystic cavity lined by neoplastic epithelial elements consisting of large cells with clear protoplasm and large hyperchromic nuclei tending to multiply and extend in an anarctic fashion. In the walls separating the neoplastic cysts from one another were these tumor cells carpeting fine strands of connective tissue stroma. In other areas the distribution of these elements suggested oniferous tubules. The cystic cavities contained a colloidal substance.

In studying the reports of the 19 cases of association of cancer and tuberculosis in the same kidney the authors find that in 9 the diagnosis was made pre-operatively in most instances the kidney was observed to be enlarged but as the tubercle bacillus was discovered in the urine the possibility of the presence of tumor was automatically excluded.

JOHN W. BRENNAN M.D.

A Case of Primitive Epithelioma of the Ureter (Un caso de epitelioma de ureter) JOSÉ PONCE ARIAS and NICOLÁS CRISTÓ PÓNC. *Arch. españ. urol.*, 1948, 4, 191

A 53 year old native of Tenerife, Canary Islands, came to Las Palmas complaining of hematuria and colicky pains in the left flank dating back several months. Cystoscopy and descending and finally ascending pyelography on the left side disclosed two kidneys, pelvis, ureters, and ureteral meatuses on the right side and an enlarged kidney with double pelvis and double ureter on the left side. However on the latter side the ureters united at the level of the fourth lumbar vertebra. The shadow of the ascending pyelography exhibited one large shadow defect at the point of union and three other smaller defects further down near the union of the ureter with the bladder. The left kidney and double ureter were removed en bloc through two incisions, one in the left kidney region and the other in the left iliac fossa. A drain was left in each incision and the operative wounds were closed around them. The patient recovered without incident.

The kidney upon being opened disclosed a mural tumor in the kidney pelvis which on histological examination proved to be an epithelioma with large clear nuclei and abundant protoplasm. The nuclei were at times double and contained large deeply staining nucleoli which were also at times doubled. There were no mitotic figures observable. The walls of the ureter at the point of union were very much thickened (2 cm.) and were infiltrated with nests of and isolated epithelial cells which in places came very close to the peripheral surface of the ureter. The three smaller shadow defects lower down corresponded to tubercular implants evidently disseminated from above.

There is only one treatment for this type of ureteral dissemination from a primary tumor of the ureter as found in the author's case in which the other kidney was determined to be functionally efficient, and that is total ureterectomy.

JOHN W. BRENNAN M.D.

Primary Carcinoma of the Ureter FRANCIS E. STOCK and CHARLES WELLS. *Brit. J. Urol.* 1948, 20, 19

Reference is made to a recent comprehensive review of the literature on primary carcinoma of the ureter. Two new cases are reported in detail.

These 2 cases are interesting because neither one was diagnosed when first seen. Case 1 was treated for a long time for what was believed to be a post-prostatectomy cystitis with hematuria. Case 2 was diagnosed as hydronephrosis of unknown origin but associated with an enlarged prostate and was allowed to go untreated on account of the general condition of the patient. In the first case hematuria was the only presenting feature while in the second there was no hematuria at any time and the patient complained only of pain in the loin some months after the hydronephrosis had been discovered. Neither case presented the characteristic triad of symptoms and signs and both patients made an excellent recovery following nephroureterectomy. Histologically both growths were papillary in nature, but in the first the volume of tumor was relatively small compared with the area of its base, while in the second the volume of tumor was large and was attached by a relatively small pedicle, from which plaques of growth could be seen spreading within the ureteral wall.

JOHN A. LOFF M.D.

Metastatic Tumors of the Ureter DAVID FREEMAN and LOUIS ERLICH. *J. Urol.*, Balt. 1948, 59, 312

True metastatic tumors of the ureter are relatively rare lesions. After a careful study of the literature the authors found a total of 37 reported cases with actual spread to the ureter via the lymphatics or the blood vessels from a primary neoplasm elsewhere in the body. Ureteral involvement from direct extension from adjacent organs is not included in this study. The criterion for inclusion in the present study was the demonstration of malignant cells in a portion of the ureteral wall in the absence of any neoplasm in the adjacent tissues. This study included not only the author's cases but also a detailed analysis of the previously reported cases. The site of the primary lesion was the stomach and prostate, each in 8 cases. In the cervix in 3 patients in the bladder, lung, large bowel and ovary each in 2 patients and in 4 patients there was a generalized lymphoma. The ureter, vagina, uterus, and urethra were the primary sites once each in the series.

While the most common symptom was pain in the lumbar region or flank (46%) it was impossible to ascertain a definite syndrome because of the concurrent involvement of the lower urinary tract by the malignant growth in most of the cases. Hematuria occurred infrequently (16%) in 90 per cent of the

patients there were metastases in other organs or structures. The most common sites were the retroperitoneal glands, the mesenteric glands, the bladder, the lungs or pleura, the kidneys, the liver and the spine.

The ureteral site of metastases was as frequently in the upper half of the ureter as it was in the lower half. There was bilateral ureteral metastases in 25 patients (60%). Of the unilateral involvements, 9 occurred in the right ureter and 6 in the left. The bilateral lesions were usually multiple and at different levels of the ureters. The ureteral lesions in 86 per cent of the patients could be felt grossly. The histologic picture of the metastatic lesions was that of the primary tumor. The most common type was adenocarcinoma which occurred in 22 or 30 per cent of the patients. Squamous-cell carcinoma and sarcoma were the next most frequent, with 6 and 3 cases, respectively. There was frequent occlusion of the ureteral lumen in both the localized nodular type and the diffuse infiltrating type of lesion. The finding of newly formed connective tissue interspersed among the infiltrating malignant cell structures in the wall of the ureter was sufficiently prominent to be an important factor in the occlusion of the ureteral lumen.

Two cases of metastases to the ureter are included in this article. One showed metastatic adenocarcinoma to the wall of the ureter. Following the postoperative death, the autopsy report revealed the primary lesion to be in the pylorus of the stomach. The second case revealed ureteral muscular invasion by squamous epithelial carcinomatous cells similar to those found in the right lung.

The authors suggest that although metastatic tumor of the ureter is not a distinct clinical entity it should be considered in the differential diagnosis in patients with obstruction of the upper urinary tract.

PETER L. SCARDON, M.D.

BLADDER, URETHRA, AND PENIS

Tonicity of the Bladder during Spinal Shock. REED M. NISSITZ and JACK LARSEN. *J Urol* Balt., 94, 89, 1945.

Injury to the spinal cord produces immediate loss of sensation and complete flaccidity of the striated muscles below the level of the trauma, with retention of urine and subsequent overflow incontinence. Heretofore, primary atrophy of the bladder has been thought to be the cause of the urinary retention that occurs during spinal shock. This assumption has been prompted by the belief that bladder muscle and skeletal muscle behave in the same manner. The bladder is composed of plain nonstriated muscle and the skeletal muscles are composed of striated muscle. The skeletal muscles and plain muscles are innervated by different nervous systems. The motor impulses to the bladder are mediated over the autonomic nervous system. The plain muscle retains its tonicity and even rhythmic contractility when completely deprived of its external innervation. It would be

unusual for the bladder composed of nonstriated muscle, to become flaccid when its motor supply had been interrupted following spinal cord injury or by chemical blockade.

The authors have demonstrated that the bladder does not become flaccid when its motor supply has become paralyzed either by chemical interruption of the nerve supply (tetraethylammonia) or by trauma, but rather the bladder retains its normal tonicity under these conditions. The distended bladder with decreased tonicity in paralyzed patients was not found to be due to the flaccidity associated with spinal shock, but rather to the decompensation resulting from prolonged distention.

Experimental work was carried out by cystometric observations on patients whose motor impulses to the bladder had been blocked with tetraethylammonium ion. Cystometric readings were made in patients in whom both the sensory and motor supply to the bladder had been abolished by spinal anesthesia. Animal experiments were carried out on the dog under light nembutal anesthesia, spinal anesthesia, and following transection and crushing of the spinal cord. Six patients were observed in spinal shock; these patients were placed on indwelling urethral catheter drainage of the bladder shortly after injury to the spinal cord.

From their observations the authors concluded that the urinary bladder muscle maintains its normal tone as well as its ability to accommodate to increasing volumes of fluid at approximately the same intravesical pressure in the condition of spinal shock. The tonic bladder observed in cases of spinal shock was thought probably to be due to the retention of urine with over-distention of the bladder for a long period of time, rather than being due primarily to the loss of the segmental reflex arc concerned with micturition.

The observations recorded in the article tend to suggest that bladder tonus is normal during the period of spinal shock provided that retention of urine with distention is not allowed to take place.

CONRAD A. KUHN, M.D.

Vesical Dysfunction. JOHN L. ENRIGHT and JOHN B. BRALL. *J Am Med Ass* 1945, 36, 693.

In 1941 the authors reported on a study of vesical dysfunction in cases of tabes dorsalis and analyzed the results of transurethral resection in 35 of the cases. In these cases the results of transurethral resection were very good. Recently they made a follow-up study of these 35 cases and of 44 additional cases of tabes dorsalis in which transurethral resection had been performed since December 31, 1940. These 2 groups of cases form the basis of their report.

It must be emphasized that it is impossible in every case to distinguish accurately vesical dysfunction caused by the tabetic state alone from that which results from hypertrophy of the prostate gland or their obstruction of the vesical neck in a case in which tabes dorsalis is only a coincidental finding and of no urologic importance. It is true that the ex-

tremes of these conditions are quite easily recognized but intermediate conditions may be difficult to classify. The chief reason for this difficulty lies in the basic neuromechanics and obstructive factors involved in the disability.

It is the authors' impression that most of the urinary incontinence in tabetic patients may be explained in two ways: (1) overflow from a distended bladder and (2) involuntary micturition caused by reflex emptying of the bladder not properly controlled by the suprasegmental conditioning reflex. The sensory components of which have been damaged. To put it simply since the patient is not aware that micturition is about to occur sufficient inhibitory impulses are not sent down from the conscious or subconscious level to prevent it.

It is apparent therefore that the over all problem of vesical dysfunction in tabetic patients is composed of three rather ill-defined parts, namely: (1) vesical dysfunction arising primarily from the neurogenic lesion caused by the tabetic state, (2) obstruction of the vesical neck in a case in which *tabes dorsalis* is only a coincidental finding and plays no part in the vesical dysfunction and (3) a combination of both factors. It is the writers' opinion that most instances of vesical dysfunction belong in the last group.

It is the opinion of the authors that vesical dysfunction associated with *tabes dorsalis* is no longer a therapeutic problem of any importance since consistently good results may be obtained by means of transurethral resection of the vesical neck. The explanation of how transurethral resection corrects vesical dysfunction in this disease seems relatively simple although some points are more or less theoretic. The elimination of residual urine is brought about by weakening the vesical neck sufficiently to permit the weakened atonic bladder aided by intra-abdominal and if necessary manual compression to expel the urine completely. The elimination of the residual urine also relieves the incontinence in cases in which the patients are suffering from an overflow type of incontinence. The explanation of the relief of incontinence that is principally an involuntary type of micturition also seems fairly simple. The elimination of residual urine increases the reservoir capacity of the bladder. The patient is instructed to micturate regularly every 3 or 4 hours to prevent undue distention of the bladder so that the chance of involuntary micturition is minimized. He is instructed to take the time and make the effort to empty his bladder completely at each micturition. In some cases in which advanced sensory damage is present, the patients never may regain the desire to micturate. Such patients must be carefully taught to micturate at regular intervals and not to wait for the desire to micturate. Inasmuch as the bladder is emptied completely at each voiding the urine may be kept free of infection therefore for all practical purposes the vesical function may be considered normal.

A word of caution is given. Inasmuch as small degrees of obstruction of the vesical neck can precipi-

tate vesical dysfunction in cases of *tabes dorsalis* small degrees of postoperative contracture may conceivably cause a recurrence of the obstruction. Because of this such patients should be re-examined at yearly intervals to determine if any residual urine is present. If it is cystoscopic reexamination of the vesical neck should be performed and any scar tissue should be excised.

Diverticula of the Bladder; A Contribution to Diagnosis and Treatment (*Divertículos vesicales, Aportación a su diagnóstico y tratamiento*) Antonio FERNANDEZ GONZALEZ *Medicina* Bogotá, 1947 p. 109.

Urinary obstruction involving the urethra or neck of the bladder should be taken care of first especially if it is of such a character as to render cystoscopy difficult or impossible. Roentgenologic examination should consist of descending pyelography which shows the functioning of the ureter. The urethral catheterization with the opaque catheter is dispensed with for the diagnosis. When the opening into the diverticulum is located the cystoscope with the mirror set at 135 degrees, so as to view the end of the instrument itself may be introduced as easily into the diverticular cavity as into the urinary bladder itself. By this means the interior of the abnormal cavity may be cleaned out and treated, and this with the cure of the urethral obstructive phenomena may be sufficient to render the patient comfortable without surgical interference.

However if surgical interference is indicated the author goes in suprapubically, either through the midline incision or by means of a lateral abdominal incision as may be indicated in the individual case and liberates the bladder from the peritoneum. This is done by the method described by Voelcker if the peritoneum cannot be totally loosened from the bladder cupula even with the snapping out of some of the superficial muscle fibers of the bladder in the process. A preliminary seminal vesiculography through an inguinal exposure of the vas deferens having clarified the relationship—usually intimate—of the diverticulum to the vesicles and vas the diverticulum is dissected loose either from the cupula to the neck or vice versa. The neck of communication with the bladder is cut through between two ligatures and the opening into the bladder is closed in the usual manner.

If the removal of the diverticular sac seems too hazardous a marsupialization of the sac to the abdominal skin surface with diathermy coagulation of the lining mucosa may be done through a separate incision removed from the suprapubic incision, however the author does not favor this method as it protracts the cure and at times gives rise to hemorrhage. In the dissection of the sac the fluid content of the bladder and sac is controlled by an assistant through a urethral catheter however the bladder is never entirely filled as the fluid content may be displaced by localized pressure from the sac to the bladder or vice versa. After the sac has been dissected out, the

bed from which it was removed is carefully inspected, the ureters, especially are subjected to careful scrutiny and if there be the least doubt as to the circulatory integrity of any portion of a ureter an immediate ureterocystostomy is done.

If the diverticulum was rather highly placed on the posterior wall of the bladder the suprapubic drainage will probably be enough; on the other hand when the sac is located low down toward the pelvic floor the transperineal paraurethral incision for drainage, as described by Illyes, is added. The bed of the removed sac is then dusted with sulfonamide and the suprapubic incision is closed around a rubber tube and two gauze drains. An indwelling catheter in the urethra is employed for a considerable period in the after care of the patient.

JORN W. BRECKMAN, M.D.

Persistent Priapism. HAMILTON BAILEY. *Br J Surg* 91:3, 35, 98.

Causes of priapism are erosive lesions vascular lesions and secondary carcinoma.

Priapism et erosus causis Priapisms executed by hanging have long been known to develop priapism. In 1823 Surgeon Major in the French Army observed in one day 4 executions by hanging. At the moment of strangulation the penis became suddenly and forcibly erect in all cases it was still half erect one hour after death.

Lesions of the spinal cord particularly traumatic lesions are occasionally complicated by priapism. Diseases of the central nervous system such as syphilis and multiple sclerosis, are cited in the literature as giving rise to priapism. Excessive doses of aphrodisiacs may produce the condition and yohimbine produces the only form of priapism in which the corpus spongiosum is more involved than the corpora cavernosa.

Priapism duct vasculosis The erection in these cases is maintained not by contraction of the erector muscles, which obstructs the venous return by pressure from without but by clotting within. It is believed that clotting commences behind the erector muscles in the formed veins that connect the venous honeycomb of the phallus with the pelvic plexus. There are frequent postmortem records of thrombosis of the deep pelvic veins in cases of persistent priapism. Thrombosis of the deep dorsal veins is the most usual cause of vascular priapism inasmuch as in 5 of 6 cases the corpora cavernosa alone are involved. When the spongiosum and glans share in the erection, the thrombosis is presumably more widespread.

Twenty per cent of cases are associated with a leucemia or sickle-celled anemia which alters the clotting mechanism. Trauma can cause thrombosis. In some cases there is no doubt that priapism followed an accident such as a fall astride. Focal sepsis is a leading cause of thrombophlebitis, yet this is an infrequent cause of thrombosis in the pelvic plexus.

The penis is usually maintained at an acute angle with the pubis. The pain is variable, in some in-

stances so great that heavy doses of narcotics are required for many days. Palpation of the glans penis usually reveals softness as compared with the solid induration of the corpora cavernosa. In 90 per cent of cases the spongiosum is not involved. The condition may occur at any time of life. Young patients are usually sufferers from leucemia or sickle-celled anemia. The elderly group includes most of those in whom a deposit of neoplastic cells is the cause of priapism.

Priapism due to lesions of the central nervous system are usually relieved by low spinal anesthesia. The surgical methods of treatment include aspiration of the corpora cavernosa, which is accomplished by the insertion of a needle into the shaft of the penis and aspiration of the stagnant, thick blood, and by repeated injection and aspiration of saline solution, removal is accomplished. Following partial or complete deflation a firm bandage is applied. It should be noted that it is highly probable that the condition will recur and the procedure must be repeated in from 24 to 48 hours. At least 3 treatments are usually required.

Incision is used in some instances and according to the author more successes have attended this procedure than aspiration. Even so, it is by no means a panacea. The author states that it is a great mistake to sew up the incision after blood and clots have been evacuated as a hematoma frequently forms inviting infection gangrene and septicemia.

Both of the author's patients, treated by incision developed gangrene despite aseptic technique. From his study of the subject he recommends incision (1) when aspiration has failed and (2) when the priapism has been present for a week or more. The operation should be carried out under general anesthesia. The incision should be not more than 0.5 inch long. It should penetrate to the center of the crus a little behind the middle of the shaft of the penis. A small hemostat is introduced into the incision and by its aid clots are evacuated by squeezing. A drainage tube is stitched in place and after sulfanilamide powder is sprinkled into the wound the penis is surrounded by a liberal damp antiseptic dressing. Prophylactic penicillin therapy is commenced at once.

The author believes that dicoumarin should be prescribed, although there is no record that it has been used in this condition. The author describes 2 cases treated by incision in which gangrene developed. The first case occurred in a man of 72 following an incision and closure. A hematoma formed which became infected and gangrene ensued. Despite amputation the patient died of septicemia. The second case was that of a man of 55 in whom an incision was made and ligation of the dorsal arteries and suprapubic cystostomy were carried out. On the fifth day it was evident that gangrene of the penis was commencing. Amputation was done the following day and his subsequent progress was satisfactory.

ROBERT O. BRADLEY, M.D.

GENITAL DROANS

Carcinoma of the Prostate with Skin and Bone Metastases Treated with Estrogens (Carcinoma prostatico con metastasi cutanee ed ossee trattato con estrogeni) GIOVANNI BARENCHI. *Minerva med* Tor 1948, 39 108.

A 54 year old man whose father had died of a gastric, and his mother of a uterine, neoplasm, had suffered vague back pains and mild attacks of fever for more than a year which had been treated at various times as rheumatism and malaria. He was quite emaciated and anemic when first seen. There were multiple nodosities scattered over the skin of the upper back and chest regions. These nodules were freely moveable in the subcutaneous tissues, measured from 3 to 4 to 8 to 10 mm in diameter and had no clearly defined borders. They were painless and the skin over them was unchanged. The eyes of the patient protruded somewhat his eyelids were edematous his pharynx was reddened and his tonsils were enlarged and irregular. Signs of pericardial and left pleural effusions were present. Both the liver and spleen were enlarged. Roentgenologic examination disclosed extensive osteoplastic shadows of the vertebrae clavicle sternum and ribs which suggested neoplastic metastases. The mediastinal lymph glands were noticeably enlarged. Palpation of the prostate and a vesiculographic examination disclosed a prostatic neoplasm. Biopsy of one of the nodules on the thorax confirmed the diagnosis of metastasis from a prostatic adenocarcinoma. In the succeeding 5 months the condition progressed in exorbitant urinary retention appeared the skin nodules grew steadily in size and new ones appeared over the neck face, scalp and abdomen. The patient was bedridden stuporous, and apparently in extremis.

Daily injections of the synthetic estrogen 4- α dipropionate of alpha beta diethylstilbene in 0.4 mgm. doses were started and after a total of 2.8 mgm had been given the skin nodules were noted to be appreciably smaller and no new ones had appeared. Under this treatment the patient put on weight and could leave his bed the pericardial and pleural effusions disappeared and the liver returned to normal size. One of the nodules were excised and histological study showed that in the superficial layers there were no cancer cells but odd-looking spaces suggesting fluid pockets which replaced the vanished neoplastic tissue. Cancer cells were found deeper but these exhibited various signs of degenerative changes. The prostate now seemed reduced in size and was less hard and irregular. This same appearance of regression was also portrayed by the roentgenologic appearance of the bone and mediastinal metastases. At a later period while the synthetic estrogen was unavailable 2 new nodules developed on the head but no regression was noted under a total dosage by injection of 5 mgm of the natural estrogen dihydrofolliculin benzoate. About a week after this treatment was stopped 2 new nodules and some red spots (new

nodules) appeared and the urinary disturbances recurred however with renewed synthetic estrogen in 1 mgm daily injections the urinary symptoms regressed rapidly and the skin nodules and reddened areas began to disappear. These regressive and renewed periods of progression of the process occurred because of refusal of the patient to take the treatment continuously or to receive large doses for 6 months at which time he left the hospital and was thenceforth treated at home. Here the injections were somewhat irregularly carried on some bone metastases developed which did not seem to respond to the drug and the patient died a little more than a year after beginning treatment.

The author thinks that on the whole the progress of the case suggests a hormonal character in view of the therapeutic results procured in this case. It is true that the lack of response to the natural preparation suggests that the efficacy of the synthetic preparation depends upon some other than the hormonal component however the treatment with the natural estrogen was not carried out sufficiently long or in sufficient doses to allow of any definite pronouncement concerning its efficacy.

JOHN W. BRECKMAN M.D.

Tumors of the Testis. LLOYD C. LEWIS, J. Urol Balt. 1948, 59 763

The varied structure of tumors of the testis suggested to the authors that no one method of treatment was adequate to control this type of cancer. Forty three per cent of 250 patients admitted to Walter Reed Hospital Washington D. C., had proved metastasis at the time of hospitalization and in addition 28 per cent of the patients eventually developed metastasis. Only a few patients with cancer of the testicle could be cured by simple orchectomy. Orchiectomy and radiation therapy proved to be a satisfactory form of treatment only in cases of seminoma.

The seminoma behaves as a clinical entity having the features of relatively slow growth delayed metastasis and remarkable radiosensitivity. The prognosis is usually good in this type of tumor. The seminoma is a rounded lobulated solid grayish white tumor which tends to compress but rarely invades the seminiferous tubules. Seminoma occurred in 109 or 43 per cent of the reported cases. Seminoma is usually found in the atrophic or maldeveloped testis. Twelve of 13 tumors in cryptorchids were seminomas. Seminomas were also found in 3 patients with traumatic or idiopathic atrophy. The author found the incidence of tumors of the testis in undescended testes to be 22 per 10,000 occurring 22 times as commonly as seen in the normally descended testes. Neither orchiopexy nor spontaneous descent of the testicle have any lessening influence on the development of tumor in a cryptorchid patient.

The classification of testicular tumors suggested by the author was based upon the embryonal form, pathological structure radiosensitivity studies and

the results of combined surgical and radiation treatment that were carried out at the Walter Reed General Hospital.

At the onset and for many months tumor of the testis may represent a painless swelling of the testicle itself. Later expansion of the capsule or trauma may produce pain. Hemorrhage may also produce pain, but the history of acute painful swelling with redness and fever characteristic of inflammatory lesions of the testicle is lacking and these symptoms may help to make the differential diagnosis between tumor of the testicle and a benign condition.

Patients with chorioepithelioma may have symptoms referable to metastatic involvement and there is no testicular mass that can be palpated. Seminoma rarely metastasizes without a palpable tumor of the testicle being present. Hormone bioassays by the modified Aschheim-Zondek technique were considered to be of little diagnostic value and positive tests were considered as confirmatory evidence only when a tumor of the testis was present, or metastasis was obviously present. Thirty-five per cent of a series of control patients without tumor of the testicle gave positive readings to the Friedman test. Thirty-four per cent of the patients with seminoma who should have secreted no gonadotropins had high readings. A positive test cannot, therefore, be interpreted as evidence of testis tumor nor of metastasis. A repeatedly confirmed positive reaction from a patient with tumor indicated a likelihood of chorionic theme being present in the tumor.

Bimanual palpation will help to make the differential diagnosis between tumor of the testicle, epididymitis, lesions of the spermatic cord, spermatoceles and lesions of the surrounding scrotum. It may be necessary to aspirate a complicating hydrocele before the testicle can be examined. When a differential diagnosis cannot be made exploration of the scrotum is imperative. Punch or needle biopsies as a means of diagnosis are condemned by the author.

Orchiectomy by the inguinal approach so that the incision can be extended to perform the radical retroperitoneal dissection after gross examination of the tumor has been done, was advised by the author. He preferred the radical orchiectomy for any type of testis tumor. Chorionic tumors metastasize by the lymphatics as well as the blood stream, therefore radical surgery in chorioepithelioma must include the long internal spermatic vessels along with the lymphatics. Lewis considered the radical orchiectomy to consist of the removal of the testis with its tunica, the epididymis, var, entire spermatic cord and the retroperitoneal lymph chain from the inguinal ring to the renal pedicles. Crossed metastases below the renal pedicles were not observed except when there was a tremendous involvement of the precaval nodes from tumor of the right testicle. Metastases from testicular tumors may skip nodes, may even skip all of the retroperitoneal nodes and appear at the supraclavicular node on the left side. Chorioepithelioma may invade the blood stream without lymphatic involvement. On the left side the lymph-

tic chain and nodes lie lateral to the aorta and pass up to the nodes at the entrance of the internal spermatic vein, thus entering into the left renal vein. Those nodes at the renal pedicle and medial to the pedicle are most frequently involved. On the right side the lymphatic pathways lead over the vena cava between it and the aorta to the most frequently involved node at the entrance of the internal spermatic vein into the vena cava. Metastatic channels lead to midline inoperable nodes situated above the renal pedicles.

The author stated that he had performed 169 radical retroperitoneal resections without operative mortality. Sixty-six per cent of the patients had no metastatic involvement of the nodes and 24 per cent of the patients had operable metastatic nodes, which were removed. In 10 per cent of the cases the nodes were found to be inoperable. Seminomas were found to be the most radiosensitive. Some embryonal tumors were markedly affected by a dosage of from 2,000 to 3,000 roentgens. Chorionic tumors were not effectively changed by roentgen therapy and irradiation of metastasis was considered to produce most discouraging results.

Röntgen therapy to be effective, required the use of a full lethal tumor dose. Prophylactic irradiation of the retroperitoneal area or of other specific areas required specific lethal tumor dosage. Using the millison volt x-ray machine it was discovered that the patients could take a large dosage and survive the immediate impact from the treatment. Some of them later developed radiation gastritis and late radionecrosis. Fourteen patients had perforated stomach and bowel $1\frac{1}{4}$ to 3 years following therapy. The relatively small lethal dose for seminoma can be delivered to the area of the retroperitoneal nodes with safety. 1,000 roentgens were considered adequate. It was not considered safe to use prophylactic irradiation for tumors which required more than a 3,000 roentgen lethal tumor dose. All patients requiring more than 1,000 roentgen units for prophylactic irradiation required the radical retroperitoneal gland dissection.

In conclusion, the author states that the treatment of tumors of the testis must be varied according to the type of the pathology. Simple orchiectomy was sufficient for benign interstitial cell tumors of the testicle. In teratoma of the testicle radical orchiectomy without radiation therapy was indicated. Simple orchiectomy plus radiation therapy was sufficient in the treatment of seminoma. One thousand units as a prophylactic dose were indicated also for seminoma, but the information gained by retroperitoneal dissection of the lymph nodes aided the roentgen therapist in planning the subsequent roentgen treatment. For undifferentiated carcinoma, adenocarcinoma, and papillary adenocarcinoma, radical orchiectomy was indicated followed by prophylactic roentgen therapy not to exceed 3,000 roentgens. For trophoblastic tumors, choriocarcinoma, and chorioepithelioma, radical orchiectomy and radiation therapy in dosages of 5,000 roentgens were used except when

inoperable metastatic nodes remained. For teratoma and malignant embryonic elements, irradiation was indicated only when inoperable metastatic nodes were found.

MISCELLANEOUS

The Significance of the So-Called Reaction of Decompression in Chronic Retention of Urine
ANNE HORN *Acta chir scand.*, 1948, 96, 397

To patients with chronic retention of urine, sudden evacuation has long been regarded as an erroneous procedure because of the likelihood of the development of symptoms from the bladder in the form of hemorrhage, from the kidneys in the form of further impairment of their function, and from the circulation in the form of a fall in blood pressure. More recently, however, certain authors have become convinced that evacuation of a chronically distended bladder is dangerous only when the kidneys do not have a sufficient quantity of liquid at their disposal. In patients who were well hydrated, neither anuria nor uremia were noted.

In the University Clinic at Oslo, Norway, it has been routine for many years to perform cystostomy to the course of the first couple of days on patients suffering from great chronic retention of urine. The patients are copiously supplied with liquids and are placed on a diet which is poor in nitrogen.

The author examined the reactions of decompression in 150 patients who had undergone this method of treatment. Fifty-eight of these patients with retention of over 400 c.c. of urine, most of whom had a considerable increase of urea nitrogen, were treated by cystostomy in the course of the first couple of days after admission. On admission the bladder was completely emptied with the use of a catheter; the method of gradual decompression was not adopted. In all but 2 cases the cystostomy was followed by copious diuresis and a decline of the serum urea. In 1 case a marked reaction of decompression with a considerable rise in serum urea was observed. This reaction was transient and without permanent injurious effect.

The second group of 42 patients had a serum urea of under 50 mgm per cent and the majority of these had a residual urine of less than 400 c.c. The diuresis which followed emptying of the bladder in this group was less pronounced than in the preceding group and no reaction to evacuation was noted. In the third group 53 patients were cystostomized following previous repeated catheterizations. The majority of these patients had been catheterized at home and the serum urea and residual urine content before catheterization were therefore unknown. These cases were not regarded as suitable for study.

From his experience with this material the author concludes that rapid decompression of the chronically distended bladder is not dangerous if the patients are copiously supplied with fluids and kept on a diet which is low in nitrogen.

ROBERT O. READLER, M.D.

Fertility in Men ROBERT S. HOTCHKISS, *J. Urol.* Balt., 1948, 59, 149.

The magnitude of male infertility is discussed. It is estimated that there are one and one-half million involuntary barren couples in the United States and that one-third of the unproductive marriages may be assigned to male faults. Thus there are one-half million husbands in the country deserving of diagnosis and treatment.

With reference to experimental and investigative work, it is pointed out that because of structural and physiological differences, information gained from animals is not applicable to the human. The work of MacLeod is mentioned from which it would appear that the essential requirements for the sperm to continue activity are an isotonic fluid and some available source of carbohydrate. The seminal vesicles supply the sugar and the prostate produces the enzymes responsible for the lysis of the semen. Moore and Gallagher demonstrated in the castrate that it takes three times as much androgen to sustain the seminal vesicles as the prostate. Heckel and Steinets showed that estrogens in the male reduce the amount of the ejaculate. Mann has suggested that since the seminal fluid contains fructose these organs must extract glucose from the blood stream and convert it to fructose. In spite of this knowledge of the prostate there is still much to be desired concerning the physiology of the prostate and seminal vesicles.

The function of the vasa and epididymes is not known, but they are apparently more than reservoirs since, as Munro has pointed out, in the rooster the hatching took place with fertilization of sperm aspirated from the testicle in 0.7 per cent of epididymal sperm in 3.5 per cent, and with sperm removed from the ampullae of the ductus deferens in 63 per cent.

Clinically it has been shown that ectopic testicles not brought down into the scrotum prior to puberty always result in sterility. Another cause of barrenness is infrequent coitus. This is borne out by the figures of Pearl who showed that between the ages of 20 and 29 years intercourse was practiced on an average of 202 times before pregnancy took place, between the ages of 30 to 39 on 190 occasions, and between 40 and 49 years on 1434 occasions prior to pregnancy. The misconception as to the time of ovulation and related coitus also accounts for some instances of barrenness.

The need of accurate tests for seminal deficiencies is well recognized. At present we have available the metabolism test to demonstrate thyroid deficiencies and a test for follicle stimulating hormone (FSH) which suggests pituitary dysfunction and permits some estimate as to whether the testicular deficiency is primary or secondary.

As to therapy the commercial preparations of hormone are grossly unreliable and too antihormones may be formed in the body so that continued hormonal therapy becomes decreasingly effective. Such an enzyme as hyaluronidase is apparently of importance and its concentration in the ejaculate is directly proportional to the number of sperm but there is no

direct evidence that it is essential for fertilization of the ovum. The clinical evaluation of this enzyme in sterility is not established.

ROBERT LICH, JR., M.D.

Oxycel in Urology. ALBERT E. GOLDBEIN and ARTHUR HOLLANDER. *J Urol Balt.*, 948 59. 195

Oxidized cellulose gauze was used as a hemostatic pack in 50 urological cases at the Sinai Hospital Baltimore Maryland. The authors state that there is no question but that it is a valuable adjunct to their present methods. They have found the gauze to be a good hemostatic agent in many areas in which they preferred not to use sutures or in which there was a generalized ooze. However it must be emphasized that where there is an obvious bleeding point, the safest hemostatic agent is the ligature or the suture-ligature. The hemostatic property of oxycel is most dependable when it can be given constant supportive pressure; thus, in the kidney it should be reinforced with a mattress suture, and in the suprapubic prostatic fossa it should have a regular gauze pack behind it. The perineal closure should be strong enough to give it support.

The authors have not been impressed with the absorbable property of oxycel. In their experience gauze becomes black when it touches blood and is quickly converted into a soft, amorphous mass. Within 24 hours, this mass has begun to disintegrate into large and small granules which drain from the body through the nearest exit—the urinary tract or the wound itself. Oxycel drainage retard complete

healing and may increase urinary drainage; the possibility of wound disruption and fistulous tract formation is enhanced by its use. In suprapubic prostatectomies, the granules are discharged through the urinary tract and the wound. Until they are completely drained from the urethra or are mechanically removed with a sound and sodium bicarbonate, they act as obstructions and cause delay in voiding. Because of this persistent drainage, complete wound healing is retarded.

JAMES A. LOFF, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Rare Case of Circumscribed Osseous Rarefaction of Elbow following Trauma of Corresponding Shoulder and Probably Attributable to a Lesion of the Parasympathetic Fibers of the Brachial Plexus (Raro caso di rarefazione ossea localizzata al Plexus (Raro caso di rarefazione ossea localizzata al Plexus) conseguente a trauma esercitato sull' spalla gomito e riferibile con grande probabilità ad intossicazione delle fibre parasimpatiche del plesso brachiale) PAOLO ZOBOLI *Boll Soc med chir Modena*, 1947 47 91

Following severe trauma a man aged 22 sustained a fracture of the neck of the right scapula. Subsequently paralysis of the corresponding brachial plexus developed causing severe pain and absence of various types of sensitivity in the entire extremity. Ten days after immobilization the patient developed pain in the right elbow which assumed a purplish color showed an increased local temperature, and became edematous. Roentgenograms revealed a circumscribed rarefaction of the bones of the elbow especially of the lower end of the humerus and the upper end of the ulna.

There were no signs of generalized osteoporosis or a similar process in the region of the trauma. The following conditions were considered and excluded: osteomalacia, Recklinghausen's fibrous osteosis, Paget's fibrous osteosis, post-traumatic osteolysis or Sudeck's atrophy and syringomyelia or essential osteolysis. The author came to the conclusion that the circumscribed rarefaction of the bones was attributable to the involvement of the parasympathetic fibers in the brachial plexus. Following paralysis the resulting hypertrophy or atrophy of muscles, the involved tissues are an easy prey to avitaminosis and vasomotor disturbances. Prolonged immobilization for about 30 days had probably contributed to the condition.

JOSEPH K. NARAY M.D.

Styloiditis of the Radius (Styloidite radiale) LUCIEN LEGER and P. GAUTHIER VILLARD. *Presse Méd.*, 1947 No. 74 858.

The 6 cases of swelling and pain on motion and pressure over the lower end of the radius were added to the 3 reported by Veyrassat and 3 reported by Mouchet seem to be all of the cases of styloiditis of the radius which have been published so far. Five of the authors' patients were women ranging in age from 30 to 60 years, and 1 patient was a man of 36 years.

The occupational nature of the malady seems substantiated in that the symptoms involved the right wrist of all the patients except 1 of the women who was left handed. Five of the authors' patients submitted to the operation of trephining and curetting out the underlying cancellous and marrow tissues of

the styloid process and all were completely relieved of the pain. The sixth refused operation. The roentgenologic examination disclosed a distal radial epiphysis with disturbances in bony structure. Under the thickened periosteum, the bony cortex appeared thinned and the density of the styloid process diminished. This porotic appearance however was not accompanied by any modification of the bony trabeculae. The patches of decalcification were so sharply delimited as to give the appearance in one case of a cystic cavity in the bone.

The curetted bone specimens exhibited in 2 instances an evident periosteal reaction, consisting of general fibrous changes and a tendency toward osteoid formation. Here the superficial disturbances of ossification were the only pathologic phenomena noted. In a third case multiple and ramified erosions could be seen. In the remaining 2 patients periosteal lesions were not noted but there were some thickening of the osseous lamellae and a mild degree of medullary fibrosis. In no case was there evidence of vascular dilatation or infiltrative cellular signs of tissue inflammation.

The etiologic theory of Veyrassat, who believed that the condition was due to multiple irritative pull on the styloid by the insertion of the ligaments and tendons at this site especially the supinator brevis tendon is tentatively accepted however the authors note that the supinator longus is also inserted near this point and suggest the theory of a malady of supination.

JOHN W. BRENTNAN M.D.

The Sternum of the Child (Radiological Studies of Its Developmental Anomalies (Le sternum de l'enfant. Étude radiologique des anomalies de son développement)) M. HANSEN. *Rev. orthop. Par.* 1947 33 475.

The sternum is visible on roentgenograms even in very young infants and the author outlines a method by which the sternum can be visualized. The body is bent forward the head is elevated the shoulders are pulled back and up and the sternum is kept in the center without any torsion of the thorax.

The shape and number of the ossification centers of the sternum indicate precisely the age of the skeleton. The manubrium of the sternum has only one center of ossification at the time of birth. The body of the sternum usually has eight ossification centers. The most proximal pair of ossification centers appears in the seventh or eighth fetal month. Between the ages of 1 and 2 years the two most proximal centers fuse and the most distal four ossification centers appear. Between the ages of 2 and 3 all four pairs of ossification centers fuse and form four large centers. In older children the density of the centers increases and is better visualized on the roentgenogram. The xiphoid process develops its center of ossification between the ages of 10 and 20.

The centers have a certain size density and a definite time when they fuse which corresponds to a definite age of the child, but these conclusions can be accepted only in the absence of dietary deficiency states, rickets, or growth disturbances.

Decalcification of the ossification centers was observed in severe pulmonary tuberculosis. Premature fusion of the ossification centers of the sternum may give rise to deformities of the thorax.

GEORGE I. REIMS, M.D.

Osteochondroma of the Ribs in a Child Suffering from Osteogenic Disease (Osteochondroma costal chez un enfant atteint de maladie ostéogénique)
J. MATTHEY, M. BLONDEAU and A. LUTTMANN. *Presse méd.*, 1947 No. 74 872

Roentgenograms of a boy of 12 years had shown tuberculosis of the hilus, first of the right, then of the left hilar regions, about 5 years previously. Six months later an exostosis of the right humerus appeared and during the following years there was evidence of a torpid growth. Three years later there appeared on the left side a round homogeneous, sharply circumscribed shadow lying subjacent to the posterior arch of the third rib. This mass grew rapidly in size, quadrupling itself in 9 months. On a roentgenogram the mass appeared roughened, indented, and containing lighter areas rather like cysts. In a special position, that is, with the back strongly arched and rotated toward the right and the scapula displaced laterally thus showing the tumor with the rays tangential to the curve of the thoracic contour the parietal character and the costal origin of the tumor could be determined. Erosion of the third rib was evident.

The tumor was removed from behind, through an incision encompassing the scapula. With the tumor were resected the posterior arcs of the third and fourth ribs. The surgeon was able to preserve intact the pleural covering of the mass. Two months later the boy was in perfect health, and the roentgen study failed to disclose local recurrence or metastasis.

On histologic examination the tumor was found to be covered with a thin fibrous capsule and to consist of cartilaginous tissue with stellate cells. The different areas of the tumor were of widely differing densities: certain zones were almost liquefied (diminished roentgen shadow density). Scattered through the mass were spicules of bone formation bordered by a certain number of osteoblasts.

The authors have reported this case because they believe—and they cite Vossa in support of their belief—that every case of association of osteochondroma with osteogenic disease, especially in a child, should be reported.

JORDA W. BREIDMAN, M.D.

Calcification of Intervertebral Discs (Disca calcificans intervertebralis) CH. LAMERIE and G. PEXILLIOT. *Rev. orthop.*, PAR 1947 331-464.

Calcification of the intervertebral discs occurs with in the nucleus pulposus or in the annulus fibrosus where occasionally actual ossification may take place.

The anterior portion of the annulus fibrosus is composed of fibrous bands which extend from the distal surface of one vertebra to the proximal surface of the underlying vertebra. They are firmly imbedded in bone by means of Sharpey's fibers. These fibers may break because of trauma or latent infection and defects occur within the annulus fibrosus. Osteogenic fibrous tissue fills these defects and "intercalary bones" develop. Preceding the formation of osteophytes or intercalary bones, changes within the annulus fibrosus are necessary.

Calcifications of the nucleus pulposus are incidental findings on roentgenograms and have no clinical significance. Any associated subjective signs are usually due to some underlying cause other than the calcification of one or several nuclei pulposi. The nucleus pulposus maintains its own blood supply up until the age of 25 and it is possible that an infection may reach this area. The calcification indicates a healing stage of an old focus of infection.

GEORGE I. REIMS, M.D.

Morphologic Variations in the First Sacral Vertebra in Cases of Lumbalization (Variaciones morfológicas en la primera vértebra sacra en los casos de lumbalización) L. GÓMEZ OLIVEROS. *Ciruj. per. Iberoam.* 1947 4 308.

The author made special studies of 100 vertebral columns and found 3 cases of sacralization of the fifth lumbar vertebra and 5 cases of lumbalization of the first sacral vertebra. He accepts the Dubreuil-Chambardel classification of this disturbance into three grades, depending upon whether the vertebra is a completely separate unit or whether it is fused to the sacrum in some manner.

This condition interferes with the dynamics of the vertebral column and may be the cause of lumbar pain, sciatica, scoliosis, and many other backache complaints.

STEPHEN A. ZIEGLER, M.D.

Pos Planus or Instability of the Longitudinal Arch.
GEORGE PERKINS. *Proc. R. Soc. M. Lond.*, 1948, 41 31.

The condition of flatfoot, or instability of the longitudinal arch (as the author believes it is more correctly termed) cannot be properly understood without a clear understanding of the respective functions of the muscles, ligaments and bones the structure of the longitudinal arch and the manner in which the stability of the arch is normally preserved.

For the longitudinal arch to be stable, two conditions must be fulfilled: (1) the body weight must pass through the center of the subtaloid-mid tarsal joint, and (2) when the body weight is being transmitted through the center of the subtaloid-mid tarsal joint, the foot must be plantigrade. I.e., all three bearing points must be on the ground.

The muscle-ligament reflex balancing mechanism is gradually acquired during the first year or two of life. Occasionally the postural activity of muscle as regards the subtaloid-mid tarsal joint is never acquired, and the longitudinal arch remains unstable.

throughout life the foot collapsing into planovalgus whenever the person stands. The three main causes of pes planus are (1) faulty postural activity of the muscle (2) an equinus deformity of the whole foot, and (3) a varus deformity of the forefoot.

From the point of view of treatment four types of pes planus deserve recognition. These types and the treatment recommended for each are as follows:

1. Mobile pes planus due to faulty postural activity of the muscle. Treatment recommended for this type is to make the patient rotate the legs out wardly while keeping the feet flat on the ground and making him stand and walk pigeon toed.

2. Mobile pes planus due to an equinus deformity of the whole foot. In boys the equinus should be overcome by a subcutaneous lengthening of the tendo achillis and while the tendon is healing the foot should be immobilized for 6 weeks in plaster with the three bearing points in the same plane, the body weight correctly aligned and the foot dorsiflexed to 10 degrees beyond the right angle. Since this procedure alters the shape of the calf it is contra indicated for girls. Raising the heel of the shoe will compensate for the equinus.

3. Mobile pes planus due to a varus deformity of the forefoot, which is associated with an architectural defect of the longitudinal arch. This is treated by forcible manipulation under anesthesia, by which the medial border of the front part of the foot is thrust downward. The foot is then put into plaster with the heel inverted as much as possible, the forefoot everted as much as possible, and the whole foot at right angles to the leg. A rockered overshoe is fitted over the plaster and the patient is taught to walk with a natural gait, little rehabilitation being required at the end of the 6 weeks of immobilization.

4. Rigid pes planus, in which (because of the faulty transmission of weight through the subtalar midtarsal joint over a long period) the joint wears out prematurely degenerative changes set in and the range of movement dwindles on account of an inelastic sclerosis of the joint capsule. If the patient cannot be made comfortable by supporting the medial border of his foot with a rigid arch support, arthrodesis of the subtalar midtarsal joint is advisable. When the fusion is solid and the foot is released from plaster the dorsiflexion stress that necessarily accompanies the act of ordinary walking is abolished by rockering the sole of the shoe.

RUDOLPH S. KATZ, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Orthopedic and Surgical Treatment of the Rheumatic Hand (Traitement orthopédique et chirurgical de la main rhumatisante). C. LAFRANCO and D. PAUZAT. *J. méd. Bordeaux* 1947 124: 537.

Generally well known orthopedic principles are used in the treatment of hands affected with arthritis. Unfortunately patients are seen too late to make complete restoration of function possible.

It is important to evaluate which structures of the hand are affected since the treatment has to be applied to the diseased parts i.e., tendons, vessels, nerves, or the articular or periarticular tissues. The general physical status and the morale of the patient has to be taken into consideration since the treatment of the rheumatic hand often is painful and has to be administered for a long period. A thorough examination includes roentgenograms, oscillographic tests, tests for sensation to warm and cold temperatures and for range of muscle contractions: hypodermic injection of histamine and adrenaline, capillaroscopy, dermographism, artificially produced ischemia and erythema caused by exposure to ultraviolet rays and by injections of the stellate ganglion.

The single most harmful type of treatment was found to be the immobilization of the fingers in extension, which often resulted in irreparably useless stiff fingers. The timing and indication of mobilization and immobilization are important. These were well outlined by Sterling Bunnell and named active splinting of the hand. The hand is splinted in a position of rest. The entire arm has to be included in the process of immobilization. The elbow is flexed, the forearm is pronated, the wrist is kept in midposition and the fingers are flexed. Splints may be used during the days when position of function of the hand is necessary and a different splint may be used at night. The splint may be made out of bivalved plaster of Paris casts, duraluminum, or stainless steel. Immobilization of the fingers should be accomplished by elastic traction with the help of banjo splints.

Stenosing tenosynovitis often requires partial excision of the thickened tendon sheath. Tenotomy of contracted tendons may be helpful in restoring use of the hand in adduction deformity of the thumb.

There are a great many indications for stabilizing, corrective, and arthroplastic surgical procedures. Stabilization of the thumb in a position of function by either an arthrodesis of the carpometacarpal joint or by an intermetacarpal bone graft (Thompson) is often very useful. Wedge osteotomy or simple arthrodesis of the wrist joint may be indicated in the correction of malposition of the hand.

Capsulotomies of the metacarpophalangeal joints often restore normal motion in these joints. Arthroplasty of the wrist is not a popular operation. Metacarpophalangeal arthroplasty is used when motion is limited more than 30 degrees. Arthroplasty of the interphalangeal joints has been successful in about 80 per cent of the cases.

Physical therapy and occupational therapy play an important part in the treatment of the hand afflicted with arthritis and are especially important in the postoperative treatment. GEORGE I. KRIS, M.D.

The Paraplegia of Kyphoscoliosis (Le paraplegie da cifoscoliosi). CARLOS PAIS. *Chir. arg. novis* 1947 31: 29.

The author presents his results in 8 cases of kyphoscoliosis treated by laminectomy and critically analyzes 50 cases found in the literature.

It is his opinion that paraplegia is much more frequent in congenital and in rachitic scoliosis than it is in adolescent and in poliomyelitic scoliosis. It is much more common in males and usually appears in the second decade of life.

Operative and autopsy observations have shown that it is not compression that produces the paraplegia, but there is sufficient evidence to show that it is primarily due to traction on the cord, the result of fixation of the nerve roots, the increased concavity of the spinal cord, and the rotation of the vertebral bodies.

The cord therefore suffers from a progressive circulatory embarrassment with resulting spinal cord softening.

The author recommends conservative management in the early cases, however if no improvement is noted he believes laminectomy is necessary. In some cases he found that it was necessary to remove some of the bone of the cavity upon sectioning some of the very taut nerve roots.

The more recent work of other authors and that of the present author has shown that operative intervention is the method of choice.

The article is accompanied by an excellent bibliographic review and is well illustrated.

CARLO SCUTERI, M.D.

Rotation Transposition Operation of the Leg (Plastic de retournement de la jambe) C. P. VAN NEE.
Rev. chir. Par. 1947 33 55

Disarticulation of the hip or high femoral amputation is indicated in malignant tumors of the leg. These procedures often leave a stump which is difficult to fit adequately with a prosthesis. The transposition of the tibia and fibula of the same leg into a defect of the thigh caused by the partial or total excision of the femur gives a stump similar to the one following a Grille type of amputation. It can be satisfactorily fitted with an artificial limb.

The rotation transposition operation was first described by Sauerbroch. It is not commonly used because of its technical difficulties. In cases of complete disarticulation of the femur the entire lengths of the homolateral tibia and fibula are used to fill the defect. In partial excision of the femur only parts of the proximal tibia and fibula are transposed.

The procedure is as follows:

1. A strip of skin measuring about 3 finger breadths in width is excised along the lateral aspect of the leg, extending from the greater trochanter to the external malleolus.
2. The malignant tumor, the affected femur and the affected areas of the soft tissues are excised at the required level. The resection of the femur is completed by disarticulation at the knee joint.
3. The foot is disarticulated at the ankle joint.
4. The lower leg is rotated outwardly in the frontal plane for 180 degrees into the thigh defect.
5. The lateral malleolus is placed into the acetabulum (in disarticulation of the hip only). The medial malleolus serves as a greater trochanter.

6. The muscles of the thigh are sutured to the muscles of the lower leg.

7. The skin edges are sutured.

A similar technique is followed in cases in which only a portion of the proximal tibia and fibula are used to replace the defect caused by partial resection of the femur. The transposed tibia is attached to the proximal femoral stump by a bone graft.

The patella is attached to the distal end of the stump, i.e., the upside-down reversal of the proximal end of the tibia. The vessels and nerves form an arc at the popliteal fossa which does not impair their function. Sensation is preserved although it is distorted.

A partial rotation transposition operation was done on the left leg of a 33 year old nurse. Partial resection of the distal two-thirds of the femur was necessary because of a myxochondrosarcoma. A complete rotation transposition operation was done on the right leg of a 31 year-old male. Disarticulation of the femur at the hip joint was indicated because of a Ewing's sarcoma. In both, wound healing occurred per primam, and the nurse tolerated a prosthesis very well which made it possible for her to return to work. She was followed up for about 3 years postoperatively. The young man will soon be fitted with a prosthesis. GEO. DE L. REISS, M.D.

FRACTURES AND DISLOCATIONS

Anatomopatologico Basal and Treatment of Bilateral Dislocation of Shoulder (II fondamento anatomo patologico e la cura della lussazione abduzione di spalla) FRANCESCO DELITALA. *Chir. org. nervim.* 1947 3 199.

The real cause of habitual dislocation of the shoulder is a disengagement of the capsule or glenoid labrum from the osseous margin of the glenoid cavity. It follows that the causative therapy consists of the union of both structures. The author published his method of attaching the capsule or the glenoid labrum to the margin of the bone by metal staples in 1932 and claims priority because Downing and also Myers described an identical operation in 1946. The operation is based on Bankart's concept of habitual dislocation of the shoulder.

The operation can be performed under local anesthesia. The patient is placed in a supine position with the involved arm abducted. The articulation is exposed through an 8 cm. long incision along the deltopectoral sulcus. Capsulorrhaphy is accomplished by the insertion of 2 nonoxidizable T-shaped staples through the capsule and the scapular margin. Silk, catgut, or metal that may become oxidized are not suitable for this purpose. The soft tissues are closed with catgut and a plaster of Paris cast is applied with the arm in adduction and in the anterior position. The immobilization is maintained for one month and after that heat massage and active motions are employed.

The author performed the operation in 30 cases with good results. JOSEPH E. NARA, M.D.

Indications and Technique in the Treatment of Fractures of the Humerus with Paralysis of the Radial Nerve (Indicazioni e tecnica nella cura delle fratture dell'omero con paralisi del nervo radiale)
LEONARDO GUL. *Chir. org. modim.* 1947 31 107

The author reports on 14 patients who had sustained compound fractures of the humerus with non union and radial nerve paralysis. The article is well illustrated with preoperative films and post operative films some after a lapse of several years. Also there are photographs of the patients showing the end results. These patients were operated upon by Scaglietti at the Centro Ortopedico e Mutilati in Bologna, Italy.

The procedure used was shortening of the humerus until the ends of the nerve could be brought together then holding of the freshened bone ends together with kangaroo tendon.

The results in 10 cases of complete radial nerve severance with radial nerve suture were complete return of function in 6 cases partial return in 3 and no return in 1. Liberation of the radial nerve was done in 2 cases with complete return of function. Repair of a severed musculocutaneous nerve was done in 1 case with complete return. Repair of the severed ulnar and median nerves was done in 1 case with uncertain results up to the time the article was published.

Periarticular fibrosis with some loss of shoulder and elbow motion was noted in a number of cases while an almost normal range of motion of all the joints was obtained in the other cases. No report was made of residual pseudarthrosis in any of the cases of fracture of the humerus. CARLO SCOPERI, M.D.

Final Results of Osteosynthesis of Fractures of the Femoral Neck Ad Modum Sven Johansson. A Study of a 16-Year Material. *GÖTTNAR ORTH. ACTA chir. scand.* 1947 96 Supp. 151

Internal fixation of fractures of the femoral neck by means of wood screws was used by Langenbeck in 1868 for the first time. In 1897 Nicolaysen described the technique of inserting a screw through the femoral neck immobilizing the patient in a plaster cast for 4 weeks and then removing the screw after 4 weeks had elapsed. It was not until 1925, when Smith Petersen introduced the three flanged nail, that internal fixation of fractures of the femoral neck became a method of choice in the hands of the skilled surgeon. Sven Johansson made the extensive dissection recommended by Smith Petersen unnecessary by using a guide wire and a cannulated nail. Waldenström called attention to the fact that the valgus type of fracture of the femoral neck healed much better than the varus type. Gammelgaard suggested that surgical intervention in the valgus type of fracture (abduction type) was unnecessary. Pauwels divided the fractures of the femoral neck into three groups: those in which the angle of the fracture line was between 0 and 30 degrees; those in which it was between 30 and 50 degrees; and those in which it was between 50 and 80

degrees and he outlined the type of treatment for each group.

A group of 314 patients with fracture of the upper end of the femur were operated upon by the author 79 per cent of whom had the varus type of fracture 14 per cent the valgus type 57 per cent the intertrochanteric, and 13 per cent the peritrochanteric. The mortality in Denmark was 15 per cent before introduction of the internal fixation of femoral neck fractures and 17 per cent after nail fixation was generally accepted.

All patients with fractures of the femoral neck were operated upon except those with the definite valgus type of fractures. Traction was applied for one week prior to the operation and particular importance was paid to leaving the leg in an externally rotated position because in this position disengagement of the fragments occurred and final reduction at the time of operation was made much easier. Immediately prior to the actual nailing procedure the leg was internally rotated until the patella pointed 25 degrees medially. In cases in which good alignment of the fragments could not be obtained in spite of traction and preoperative maneuvers the operation was cancelled and the patients were returned to the ward and additional traction was applied. Spinal anesthesia was found satisfactory in most cases. The guide wire was inserted by manual guidance and the nail inserted after the position of the guide wire was found to be satisfactory on a roentgenogram. The patients were kept in bed for 4 weeks postoperatively and physical therapy was started one week after the operation. Approximately every fifth patient showed some change of the position of the fragments postoperatively. The femoral head was allowed to rotate posteriorly to some degree but too much retroversion caused anterior displacement of the fragments and an anterior position of the nail which factors contribute to the postoperative slipping of the nail. It was found to be better to keep the nail in a more posterior position at the time of nailing.

Technical errors at the time of surgery were found to be the predominant factors in the postoperative slipping of the femoral head (i.e. inadequate reduction, unsatisfactory position of the nail or an unsuitable length of the nail). Another less frequently found cause was slipping or breaking of the nail. Changes in the femoral head itself caused the head to change its position postoperatively in a large percentage of cases. Schmorl stated that use of the leg favors callus formation. Too much motion of the leg was a frequent cause of nonunion of fractures of the femoral neck. Age, early ambulation and the patient's weight had no bearing on postoperative slipping of the head.

In the group of 314 cases 66 patients showed postoperative slipping of the head. Only 38 were reoperated upon. Of these, 16 had aseptic necrosis of the head, 13 had aseptic necrosis of the femoral neck and 15, traumatic arthritis. At the time of the second operation a favorable position of the fragments was

unobtainable as a rule, and the nail slipped out postoperatively in every case.

Most workers suggest an osteotomy as the procedure of choice in cases in which aseptic necrosis of the femoral neck or head followed the primary surgical procedure. In cases in which the head and neck showed no destruction in spite of nonunion, renailing or nailing and bone graft have been recommended.

Evaluation of the final results was complicated by the fact that a number of the patients most of them 60 years old or older died or became bedridden because of cerebral accidents. Healing of the femoral fractures was characterized on the roentgenograms by bridging bone across the fracture site. Lack of full motion in the hip was not as disabling as pain. Age had no influence on the final outcome. Aseptic necrosis of the femoral head was found in 38 per cent of all patients treated by internal nail fixation. The first sign appeared on the roentgenogram within 3 to 5 months postoperatively. It took from 1 1/2 to 3 years for the repair of the femoral head by creeping substitution. A large number of the patients showing aseptic necrosis of the femoral head had at one time or another dislocation of the head i.e. either at the time of injury or at the time of manipulation or internal nail fixation. Corrosion or breaking of the nail or age of the patient had no influence on the occurrence of aseptic necrosis of the femoral head. Pain is the predominating complaint in aseptic necrosis of the femoral head.

Resorption of the femoral neck was due either to squashing of the neck at the time of injury especially its posterior aspect, or to instability at the fracture

site following surgical intervention. Sixty-nine per cent of all unstable nail fixations showed resorption of the femoral neck.

The outward slipping of the nail was found to be due to inadequate insertion and resorptive processes in the femoral neck. Extrusion of the nail occurred in 78 per cent of all renailings and in 29 per cent of primary nailings of femoral neck fractures.

It was found that Swedish steel or chromiun-nickel steel had greater noncorrosive properties than vitallium.

GEORGE I. REINE, M.D.

ORTHOPEDICS IN GENERAL

Restoration of the Thumb. ARTHUR J. BARSKY.

Surgery 1948, 53: 227

The losses of the thumb are divided into partial losses in which no more than the distal phalanx is lost, subtotal losses, involving approximately both phalanges of the thumb and total losses meaning that not only are both phalanges missing, but that all or most of the metacarpal of the thumb is also absent.

The author describes a successful technique for restoring the thumb by means of a finger transplantation and nerve suture. The use of different types of pedicled skin grafts, bone grafts, and substitution toe grafts is described. A simple practical work prosthesis is described and shown. Phalangization of the thumb metacarpal is often very helpful in aiding the prehensile function of the thumb. The details of the armamentarium and surgical technique are completely described.

DAVID H. LEVITZMAN, M.D.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

Operative Exposure of the Blood Vessels in the Superior Anterior Mediastinum HARRIS B. SHU
MACKER, JR. *Ann. Surg.* 1945, 127, 464.

The author believes that each operative exposure of the superior anterior mediastinum must be individualized but insists that all exposures must be ample if one is to carry out a procedure which offers safety to the patient. In any contemplated excision of an aneurysm or arteriovenous fistula, it is essential to isolate the vessels both proximal and distal to the lesion before attacking the lesion itself.

An incision is made from the midpoint of the clavicle down over the sternoclavicular joint and continues down the midline of the sternum to the level of the third or fourth interspace. The inner third of the clavicle is excised and the sternum is split longitudinally down to the second or third interspace. The edges of the sternum are retracted with bone hooks until the underlying structures are freed with blunt dissection, and then a small rib spreader is substituted. This gives an adequate exposure of the innominate veins superior vena cava, arch of the aorta, innominate artery subclavian artery carotid artery and phrenic and vagus nerves.

After the vascular surgery is completed the wound is closed in layers. The sternum is re-approximated either with wire or silk sutures. The clavicular perosteal bed is carefully closed with interrupted silk sutures. In some cases the excised portion of clavicle has been replaced in the form of bone chips. The overlying muscles, fascia, and skin are closed with silk.

DANIEL ROGE, M.D.

Disasters following the Operation of Ligation and Retrograde Injection of Varicose Veins. JOSE
PHILIP C. LUKE and G. GAVIN MILLER. *Ann. Surg.*,
1945, 127, 476.

The authors cite 21 illustrative cases representative of untoward reactions which infrequently occur following ligation and retrograde injection of the saphenous vein for treatment of varicosities. These complications are divided into those resulting from deep venous thrombosis and those due to operative difficulties and errors.

The formation of thromboses constitutes the larger group of complications caused probably by two factors: reduced muscular activity postoperatively with consequent slowing of the venous return and injection of too large a quantity of sclerosing fluid.

Operative errors include clamping of the femoral vein severe hemorrhage injection of sclerosing material into the wrong vessel and occlusion of major arterial trunks by spasm and thrombosis, causing gangrene of the entire leg or a particular area.

Both types of complications can result in disability of varying degree and fatality. The following sug-

gestions are advocated to reduce the morbidity of this operative procedure: (1) a local anesthetic only should be used and the patient should walk immediately following operation (2) no more than 5 c.c. of sclerosing solution should be injected.

C. FREDERICK KITTLE, M.D.

Some Observations on the Early Management of Gunshot Wounds of the Arteries DOUGLAS
LESLIE. *Austral N. Zealand J. Surg.* 1948, 17, 163.

The observations on which the present article is based were made by the author during his experience (9 months) with forward surgical teams in New Guinea and in the Dutch East Indies, and during a further period of 24 months with advanced general hospitals in the same areas. The author classifies the pathology of arterial injury in the following:

The "near miss" After a high velocity projectile has passed close to an artery the vessel may sometimes be seen to be in spasm without having any visible organic damage in its walls.

The contused artery The contused vessel when exposed, is seen to have a patch of bruising in its wall. The intima may be partly ruptured and there may or may not be a thrombus present in the lumen. There is nearly always some arterial spasm present. There is no primary bleeding from the injured vessel but if the wound becomes septic, secondary hemorrhage is probable. Also traumatic false aneurysm may follow such an injury.

The partially divided artery In the partially divided vessel there is a lateral opening involving a certain fraction of its circumference.

The severed artery A completely severed artery often stops bleeding spontaneously even if it is as large as the axillary or common femoral artery.

The ischemic limb Some limbs survive only to require later amputation because of ischemic contracture which renders them painful and useless. An ischemic limb is particularly susceptible to all types of infections, of which the most important are those by anaerobic organisms.

The objects of treatment are: (a) to save the patient's life (b) to save his limb (c) to prevent as far as possible the later complications—sepsis secondary hemorrhage traumatic false aneurysm arteriovenous communication and ischemic contracture.

In instances in which there is a relatively small external wound near the course of a large vessel with signs of impairment of the distal circulation in that limb such impaired circulation is due either to a complete lesion, or if the lesion is incomplete to the presence of intravascular clot, pressure or periarterial subfascial hematoma or collateral spasm. The complete lesion calls for ligation above and below and for evacuation of the surrounding clot so as to decompress the fascial compartment and its valuable muscular collaterals. The incomplete lesion also

calls for ligation and decompression (only this can relieve pressure on the collaterals) and this also will help to release collateral spasm and enable the collateral circulation to expand. This procedure will also reduce the incidence of the late complications—traumatic false aneurysm, secondary hemorrhage and arteriovenous communication, all of which carry with them an appreciable limb mortality. In cases in which a small external wound is seen near a large vessel, but the distal circulation is normal, the decision whether to operate or not is made purely on the characteristics of the wound itself and if this is minute and there is no evidence of tension beneath the deep fascia, operation need not be considered. In some of these cases the late complication of arteriovenous communication occurs and therefore any artery that might pass near a wound track should be examined with a stethoscope. If an intact vessel is seen traversing an infected wound, the arteries should be tied when the abscess is drained.

THE PROBLEMS OF THE SMALLER VESSELS AT SPECIAL SITES

The right calf. A gunshot wound through the posterior fascial compartments of the leg is often associated with subfascial bleeding from the posterior tibial artery. Some of its branches the hematoma infiltrates the muscles widely and produces considerable swelling of the leg. Such a calf is an ideal site for the occurrence of aerobic infection and there is also sometimes impairment of the circulation in the foot.

The bleeding hand. A hematoma in the hand requires decompression just as does one in the thigh apart from the possibility of infection, a hematoma beneath the palmar fascia can cause serious interference with the circulation in the fingers. By properly placed incisions it is better to attack the bleeding point than to trust to proximal ligation.

The bleeding buttock. A local exposure must be made as much as the dangerous gluteal muscle mass as in the hope of finding the bleeding point. It may be necessary to put a temporary pack in the opened buttock and then to obtain hemostasis by ligation of the internal iliac artery. Making an opening of secondary hemorrhage cites ligation of the internal iliac artery for bleeding buttock as the only justifiable example of proximal ligation for hemorrhage at a distance. It may also be required for primary hemorrhage at this site. The main trunk of the vessel must be tied rather than one of its divisions, as is often done. If whether the bleeding is from the superior gluteal (posterior division) or the inferior gluteal (anterior division) muscle.

C. FRED GORING, M.D.

The Problem of Maintaining the Continuity of the Artery in the Surgery of Aneurysms and Arteriovenous Fistulas. HARRIS R. SNOWACKER, J.
A. Surg. 9:18 27 307

The author reports his experience with the surgical treatment of aneurysms and arteriovenous fis-

tulas (about 300 cases). The report deals specifically with 34 cases in which some type of reparative procedure was accomplished. Early in the author's experience he cared for 138 patients with involvement of the innominate, common and extracranial portion of the internal carotid, subclavian axillary brachial iliac, common femoral femoral, and popliteal arteries, in which continuity of the blood supply is desirable. Repair was performed in only 4 (2.9%) of these. He then determined to carry out a repair in every instance in which this could possibly be performed without sacrificing the collateral arteries and without leaving in situ obviously badly damaged portions of arteries. This resulted in the repair of arteries in 30 of the last 57 cases (52.6%). Four types of repair were carried out: (1) ligation or transfixion of the fistula, (2) lateral arteriorrhaphy, (3) end-to-end suture and (4) vein transplantation. The principle of evertting mattress sutures of either fine silk or cotton was employed. Anticoagulants were used in most instances of lateral suture, end-to-end suture and vein graft. In some cases sympathectomy was employed as an aid to circulation.

Thirteen patients with arteriovenous fistula were treated by ligation and transfixion of the fistula with maintenance of the continuity of the artery. The ages of the patients varied from 19 to 45 years, and the duration of the fistulas was from 4 to 11 months. The fistula was between the carotid artery and jugular vein in 3 instances, between the popliteal vessels in 4, the femoral in 5 and the axillary in 1 case. In 8 cases sympathectomy was performed because of poor collateral circulation. Anticoagulants were used in 3 cases. The size of the fistula varied from 3 to 1 mm. in diameter. In 6 cases sacular aneurysms were present. These arose from the vein in 3 cases, from the fistula in 2 and from the artery in 1 case. In one patient in whom simple transfixion of the fistula was performed, recurrence of the bruit and thrill was evident 2 days after operation. The fistula was excised with quadruple ligation 2 weeks later with good results. The results in all cases were excellent.

In 5 cases the arterial defect was repaired by lateral suture. In 2 of these the defect was a traumatic arterial aneurysm, and in 3 an arteriovenous fistula. The brachial artery was affected in 1 case, the subclavian artery in 2 cases and the femoral artery in 2. The arterial defect were from 3 mm. to 13 mm. in length. Two patients received anticoagulant therapy. One patient with a sacular aneurysm of the brachial artery developed a hemorrhage on the thirtieth postoperative day, the artery being bathed in a pool of pus. This was excised and the result was satisfactory. One patient with arteriovenous aneurysm of the middle third of the femoral artery, a thrombosis developed 3 hours after operation following excision of the thrombosed vessel, the result was good. This occurred presumably because of the extent of damage to the artery and the narrowing of its lumen after closure of the defect. The rest achieved satisfactory results.

In 10 cases the artery was repaired by end-to-end suture. The ages of the patients ranged from 19 to 35 years and the lesions varied in duration from 3 to 85 months. Eight of these patients had an arterial sacular aneurysm and 2 had an arteriovenous fistula. The lesion involved the brachial artery in 7 cases, the axillary artery in 2 and in 1 patient a double fistula was present between the femoral and the profunda femoral arteries and femoral vein. In one patient sympathectomy had been performed before operation. It was necessary to excise segments of artery ranging from 1.5 to 3 cm. in length. In lesions of the axillary and brachial vessels length of artery was gained by adducting the arm to the body and flexing the forearm. This position was maintained postoperatively. In one case in which the fistula involved both the femoral profunda and the arteries the divided ends of the femoral artery could not be approximated. It was, however, possible to approximate without tension the proximal end of the profunda to the distal stump of the femoral artery.

The patients were followed for a period of from 1 to 5 months and in 8 patients the result was successful as regards the patency of the artery.

In 6 cases the arterial defect (aneurysm in 3 and arteriovenous fistula in 3) was repaired by vein transplantation. The patients ranged in age from 19 to 36 years. The brachial artery was involved in 1 patient, the popliteal artery in 1 and the femoral artery in 4 patients. Sympathectomy had been performed in 2 cases. The sources of vein grafts were the saphenous and femoral veins. All patients were given anticoagulants. Patency was maintained in all but one case.

The reparative procedures were, therefore successful in 28 of 34 cases. The failures were evidenced by recurrence of fistula and thrombosis of repaired segments. Postoperative hematoma developed in 4 patients all of whom were receiving anticoagulants. Patency was determined by clinical examination, arteriography and oscillometric studies. One unexpected finding was that in general oscillations were about equal in the extremities operated upon and normal in those cases in which a fistula was simply ligated and transfixed, slightly reduced in lateral arteriorrhaphy and reduced to a somewhat greater degree in cases of end-to-end suture or vein grafting. The cause of this is unexplained. In any event there was little or no evidence of any functional circulatory impairment. In general, the functional results of operative repair were found to be excellent.

The author believes that in addition to the usual considerations of arterial repair, 4 mattress sutures placed equidistant are better than 3 in end-to-end anastomosis, and that everting interrupted mattress sutures are best for the repair. He is inclined to favor suture methods rather than mechanical aid in arterial repair. The author's experience with the nonsuture methods has not been very satisfactory.

LEROY J. KLEINWASSEL, M.D.

Complete Transposition of the Aorta and the Pulmonary Artery C. ROLLINS HAMILTON and ALFRED BLALOCK. *Ann. Surg.* 1948, 127 385

The authors point out that in complete uncorrected transposition of the great vessels the aorta arises from the ventricle receiving systemic venous blood and the pulmonary artery arises from the ventricle receiving oxygenated blood—a condition incompatible with continued existence. In most instances, however, some communication exists between the two circuits through an interventricular or interatrial septal defect, patent ductus arteriosus, or by the passage of pulmonary venous blood into either vena cava, thus permitting the patient to survive for variable periods, an average duration being 19 months for all the associated abnormalities. An interventricular septal defect plus a patent interatrial septal defect gives the best prognosis; an interatrial septal defect alone provides the next longest life expectancy and a patent interatrial defect alone the third most favorable life expectancy.

The authors have endeavored to develop a surgical method of treatment of complete transposition by effecting the return of the blood of the pulmonary vein into the vena cava or the right auricle, as such a condition has been occasionally detected as an isolated abnormality at operation or autopsy in patients who have shown no evidence of cardiovascular difficulty and has been described as a beneficial adjustment in transposition. These studies demonstrate the feasibility of anastomoses of the veins from the two upper lobes of the right lung to the superior vena cava, whereas the anastomoses to the right auricle tended to become occluded. Catheterization of the heart chambers and superior vena cava established the effectiveness of this shunt in returning blood to the right side. Thus far the authors have been unable to prepare an animal with complete transposition so the effectiveness of such a shunt actually in this state has not been established but this method may offer a possible approach to the surgical treatment of complete transposition of the great cardiac arteries in man.

EDWARD H. CAMP, M.D.

BLOOD TRANSFUSION

Normal Red-Cell Survival in Men and Women SHEILA T. CALLENDER, E. O. POWELL, and L. J. WITTE. *J. Path. Bact. Lond.* 1947 59 519

The authors present the results of their studies concerning the survival of transfused erythrocytes by the method of differential agglutination in 4 normal females and 2 normal male subjects of group A from whom blood was removed and replaced by blood of group O.

The curve of decay of the transfused cells was linear in men and appreciably curved in women. The average lives of the cells were 63 and 54 days respectively.

The relation has been deduced between the decay of transfused cells and the law of survival of the in

dividual erythrocyte on the assumption that two types of destructive factor are normally operative.

It is concluded that most red cells live for approximately the same time 120 days in both men and women.

Extraneous factors cause the loss of some cells before they have reached this age limit. The loss is greater in women than in men by the equivalent of 400 c.c. of blood per month—more than can be ascribed to menstruation.

The average age of cells at death is tentatively assessed at 90 to 100 days in women and 110 to 120 days in men. **LEROY J. KLEIDMANER, M.D.**

The Causes of the Delay in Coagulation in Hemophilia; Role of the Platelets (Sur les causes du retard de la coagulation chez l'hémophile. Rôl des plaquettes) M. BOURGEOIS. *Rev. hemet* 1947 : 493.

In summarizing work previously reported by other investigators, the author starts with the assumption that the delay in coagulation in hemophilia is due to a lack of some factor rather than the presence of no inhibitory substance. The blood fibrinogen seems to be qualitatively and quantitatively normal. There is no lack of calcium ion and the prothrombin level is apparently normal. There seems to be a disturbance in thromboplastin but it has not been previously determined whether this is due to a defect in the platelets or in some noncellular constituent of the plasma.

Four patients with hemophilia were studied to determine the role of the platelets and the origin of the antihemophilic factor. Two plasma fractions were prepared from citrated blood—one with a high platelet

count, and the other essentially free of platelets. These fractions were recalcified and the coagulation time was measured. When normal plasma was used, there was little difference in the clotting time between the platelet rich and platelet-free fractions. With hemophilic plasmas the coagulation time was two or three times as long for the platelet-free as for the platelet rich fraction. Heparinized normal plasma gave results similar to those of hemophilic plasma.

When the platelets were broken down by agitating the platelet rich plasma with powdered glass the coagulation time of both normal and hemophilic plasma was reduced. However, the clotting time of the hemophilic plasma was still considerably more prolonged than that of normal plasma. Heparinized normal plasma exhibited similar behavior to hemophilic plasma when the platelets were fragmented.

From these observations the author concluded that the coagulation time of normal plasma is almost independent of the level of platelet thromboplastin. However the platelet thromboplastin of hemophilic plasma caused a marked acceleration of the clotting time of platelet free normal plasma. The platelet thromboplastin of normal plasma had a less marked effect. Apparently the plasma in hemophilia lacks some factor and in the absence of this factor the platelet thromboplastin is less active, even when it is in excess. This antihemophilic factor seems to be necessarily of nonplatelet origin. The appearance of active thromboplastin requires the joint action of a plasma factor and a platelet factor.

THEODORE B. MARSHALL, M.D.

SURGICAL TECHNIQUE

OPERATIVE SURGERY AND TECHNIQUE POSTOPERATIVE TREATMENT

The Risk of Surgery in Heart Disease. DONALD R. MORRISON *Surgery* 1948, 23 561

The author made a study of 150 patients who had been subjected to 189 operations. All cases in this series answered the requirements of the American Heart Association for inclusion in the group of cases of rheumatic heart disease (1) a history of any of the manifestations of rheumatic fever (polyarthritis, chorea, muscle or joint pains, subcutaneous nodules) and (2) evidence of a characteristic structural lesion of the heart (carditis, cardiac valvular disease, adherent pericardium).

For inclusion in the group with arteriosclerotic heart disease it was required that the patient present signs or symptoms of cardiac abnormality—enlarged heart, a previous episode of failure, previous coronary occlusion, anginal attacks, abnormal dyspnea, orthopnea, etc.—without a history of rheumatic fever, syphilis, or thyroid disease and supported by at least one characteristic clinical finding such as cardiac enlargement shown by roentgen examination, electrocardiographic changes, or congestive heart failure. Postmortem evidence of coronary sclerosis, and definite electrocardiographic findings such as inverted T waves, diphasic T waves, or auricular fibrillation or flutter and heart block in the absence of other etiologic possibilities, have been accepted as proof of the disease without the requirement of any symptoms. Patients with symptoms of heart disease and no other more specific findings of cardiac arteriosclerosis were not included.

Three hundred and eleven patients were found to answer these requirements and they were subjected to 485 operations.

SYPHILITIC HEART DISEASE

Seventeen patients had 27 operations. Of these, all except 3 had a +4 Wassermann reaction and a widened aorta confirmed by roentgen examination. This study made possible the following conclusions:

1. The risk of surgery in rheumatic heart disease is not great. What risks there are seem to center in certain types of patients with rheumatic heart disease, namely those over 35 years of age, those with fibrillations, and those with a high functional classification. No relationship to risk could be demonstrated for operating time or the combined presence of aortic and mitral lesions.

2. The risk of surgery in arteriosclerotic heart disease is considerably greater and seems to be centered in the etiologic diagnosis. It does not appear to be significantly modified by the various anatomic, physiologic, or functional factors except that disorders of cardiac rhythm and poor renal function produced higher risk rates. Patients with arterio-

sclerotic heart disease showed a mortality rate four times that of rheumatic heart disease.

3. The risk of surgery in syphilitic heart disease cannot be accurately determined in the small number of cases available. However the evidence suggests that the risk is less than in arteriosclerotic heart disease but it is greater than in rheumatic heart disease.

4. No single anesthetic agent is definitely superior for patients with heart disease, however it seems that local anesthesia should be used if feasible and spinal anesthesia avoided if possible.

ANTISEPTIC SURGERY; TREATMENT OF WOUNDS AND INFECTIONS

The Treatment of Local Pyogenic Infections with Anticoagulants (Heparin) PH. SANDBLÖM, G. EKSTRÖM and O. QUIST *Acta chir. scand.*, 1948, 96 323.

Twenty four patients with local pyogenic inflammatory processes were treated with heparin on the assumption that the infection-combating powers would have better access to the foci of disease when the thrombus formation in the small vessels and the deposition of the fibrin in the tissues had lessened. One-half of the patients, especially those with infection of a diffuse, phlegmonous character, had an unusually favorable course in connection with the heparin treatment. JOHN J. MALONEY, M.D.

ANESTHESIA

The Local Anesthetic Properties of Amidone (Dolophine). FRANK G. EVERETT *Anesthesiology* 1948, 9 115.

Considerable structural similarity exists between meperidine (demerol) and amidone. On this basis one would expect that these compounds would have similar pharmacological properties. This has been demonstrated with respect to analgesia, spasmolysis on isolated intestines and certain parasympathetic actions.

The author reports his observations on the local anesthetic action of cocaine, meperidine and amidone. He compared the action of these compounds by (1) noting their anesthetic effect on the cornea of the rabbit, and (2) observing their effect on the human intradermal wheal.

Amidone was found to possess strong local anesthetic effects in the concentrations used: 1% and 5% per cent solutions of the hydrochloride salts of the agents tested were used for anesthesia of the rabbit's cornea, and 0.25 per cent solutions of the hydrochlorides of the three agents were used for the human intradermal wheal anesthesia. Amidone produced a duration of anesthesia of the rabbit's cornea approximately equal to that with cocaine, while the dura-

INTERNATIONAL ABSTRACTS OF SURGERY

n of anesthesia for the human intradermal wheal is slightly longer with amilone.
Meperidine in comparison with cocaine and amilone, produced incomplete anesthesia of the rabbit's nose and a much shorter duration of anesthesia in human skin.

The irritant properties of both amilone and meperidine precludes their practical use at present as local anesthetics.

MARY KARP M.D.

Chondrocurare in Inhalation Anesthesia (O
kondrocurare na anestesia por inalação) Ugo
PIMENTA GUIMARÃES, AUSTOINIO PARAY E SOUZA,
and OSWALDO VITAL BRAZI Res. Brasil 41
17 2

A product called chondrocurare which is dimethyl-ether-hydrochloride of methyletheberine, was found useful by the author as an adjuvant in inhalation anesthesia. The drug is given intravenously in the form of a 3.000 solution in normal saline solution. In exceptional cases intramuscular injections may be given. Apparently the rate of injection is of no clinical importance. As a rule the drug is injected at the same speed as Intocustrin.

Muscular relaxation is obtained within from 30 to 60 seconds after the intravenous administration of chondrocurare, and within 15 minutes when the intramuscular route is employed. Experiments on mice showed Intocustrin to be more effective than chondrocurare, but in man equal volume doses of both substances have an identical effect. The effect of one unit of curare or of 1 mgm. of chondrocurare corresponds to that of 0.5 mgm. of chondrocurare. The drug is obtained from the plant chondrodendron platyphyllum tomentosum. The first men-
tioned plant grows in Brazil.

The author employed the drug in several dozens of cases as a supplement to cyclopropane and oxygen or cyclopropane, ether and oxygen, or nitrous oxide and oxygen. A satisfactory relaxation was obtained in 58 per cent, and an excellent one in 43 per cent of the cases. No untoward effects were observed by the author. The effect of chondrocurare on the blood pressure, pulse, and respiratory movements is identical to that of curare proper.

JOSEPH K. NARAY M.D.

cessive secretions. Open drop administration of either still remains the anesthetic method of choice in children. For the geriatric patient the dose of morphine should be greatly reduced or omitted completely and demerol (from 50 to 75 mgm.) or a barbiturate should be given in conjunction with atropine. Local and regional blocks are the choice of the author in minor procedures. Hypoxia should be avoided.

Coexisting pathology which increases the surgical risk may determine the selection of the anesthetic agent and technique. Conditions such as diabetes and anemia should be controlled prior to extensive orthopedic procedures. In patients with heart disease and some evidence of loss of compensatory mechanism, local or regional block anesthesia should be used whenever possible. If the pulse rate becomes markedly irregular from 30 to 70 mgm. of procaine should be injected into the veins immediately to diminish the irritability of the conducting mechanism of the heart and revert the disturbed rhythm to a regular sinus rhythm. In a patient with moderately severe diabetes who is under control, an infusion of 1000 c.c. of 5 per cent glucose in normal saline solution with 15 units of regular insulin is usually given 4 hours preoperatively or during the operation. Care must be used to distinguish between the shock of operation and insulin shock.

The type and site of certain orthopedic procedures add to the anesthetic problems and call for increased vigilance and better methods of control. Before spinal fusions the patient should be intubated, and controlled respiration should be employed for the greater part of the operation to augment the exchange of gases. For closed reduction and internal fixation by nailing of the neck of the femur a weak sodium pentothal drip solution (from 0.1 to 0.2%) in 5 per cent glucose and distilled water is used with a 3 per cent gas-oxygen mixture.

Traumatic and hemorrhagic shock should be controlled early and blood loss should be replaced as it occurs.

PHYSICOCHEMICAL METHODS IN SURGERY

ROENTGENOLOGY

The Geometric Problem of Stratigraphy (Il problema geometrico della stratigrafia) ALDO PERUSSA. *Radiol med Milano* 1948 34 1

The author furnishes a preliminary report of an extensive research carried out in collaboration with a mathematician and pertaining to the geometric problems of stratigraphy.

To allow a comparative study of various modalities of stratigraphy it is essential to consider the geometric data. Stratigraphy can be accomplished only if a certain law regulating the reciprocal relations between the focus and the film is observed. Theoretically an infinite number of solutions complying with this law is conceivable each being determined by the degree of the displacement of the focus.

The author discusses the characteristics of a single concrete modality of stratigraphy. Each modality is a complex function of the displacement of the focus and is related to the shape and thickness of the layer traversed by the x rays.

The author discusses the possibility of an exact geometric and numerical expression of various modalities of stratigraphy. Such mathematical definition of the various modalities is based essentially on the study of surfaces presenting an equal degree of vanishing of shadows.

ARTURO F. CIPOLLA, M.D.

Radiographic Anatomy of the Normal Thymus with Pneumomediastinum (Saggio di anatomia radiografica del timo normale col pneumomediastino). GOFREDO GIANCARDI. *Radiol. med.*, Milano 1948, 34 27

The author studied the normal anatomy of the thymus by comparing his findings obtained with an anterior pneumomediastinum followed by roentgenography with those found at autopsy. Eleven cadavers were used: the patients varying from a few days to 84 years as to age but having no clinical symptoms of thymus involvement.

With the cadaver in the horizontal position roentgenograms were taken in two projections. A pneumomediastinum was done by the technique of Condorelli and this was followed by a repetition of the roentgenography.

Finally an autopsy was done: the condition not only of the thymus and its compartment being ascertained but also that of the mediastinum and lungs.

The comparison of the roentgenograms with the anatomy of the thymus found at autopsy showed no exact similarity. An opaque band was seen on the lateral projected roentgenogram which was produced either by the thymus or by retrosternal deposits of fat.

Accumulation of Blood Simulating Primary Bronchial Cancer. JOHN D. CALL and PORTER P. VIM. *SON. Am. J. Roentg.*, 1948, 59 227

An area of increased density in a chest film is usually interpreted as being due to a tumor in inflammation. Rarely is an increased density in chest roentgenograms due to an accumulation of blood.

In the case reported the patient coughed up a considerable amount of blood. Chest films revealed a density in the right base which was interpreted as being due to a tumor. Bronchoscopy revealed a simple bronchial erosion which was treated by curettage dilatation and the administration of neosynephren. Follow-up chest films, 7 months later failed to reveal any evidence of pathology.

MAURICE D. SACHS, M.D.

Variations of the Diaphragmatic Contour. Their Cause and the Diseases Which They Simulate (Variaciones del contorno diafragmatico. Su genesis y enfermedades que simulan). M. CERQUERA GOMEZ. *Rev. esp. enferm. op. digest.* 1948, 7 1

The author presents a detailed and extensive discussion of the literature concerning the variations of the diaphragmatic contour apropos of a case diagnosed as hydatid cyst of the hepatic convexity. He discusses the functional exploration of the diaphragm its physiologic and pathologic variations, and suggests interesting conclusions. He calls attention to the scarcity of literature with regard to this problem even in roentgenologic journals and texts.

The variations of diaphragmatic contour may be due either to supradiaphragmatic, diaphragmatic, or infradiaphragmatic processes.

The survey of the diaphragm should include fluoroscopy and roentgenograms in anteroposterior oblique and lateral positions in deep inspiration and in expiration as well as transverse roentgenograms in anteroposterior and lateral projections. The lateral position is recommended especially. In some instances it will be necessary to produce a pneumoperitoneum to rule out any hepatic process.

The theories of Minkowsky, Testut and Plesch about the physiology of the diaphragm are discussed but are not accepted. Instead the following conception is proposed: the diaphragm is constituted of two different muscular groups: a posterolateral which pulls the diaphragm downward and an anteromedial which helps to raise the sternum and the seventh and eighth ribs: the two actions succeeding each other immediately: first the posterolateral segments contract and pull the central tendon downward and then with the fixed point in the central tendon immobilized by the abdominal pressure the anteromedial segment lifts the chest wall.

The classic contour of the right hemidiaphragm may show two main variants: a type of division in two arcs with different levels (the most frequent one)

and a type of digitation (which is rarer) which is seen only on the left side.

These variations were explained by Thomas and Assman Slinger, and Bolkan and Pendergram and Hodges as physiologic ones due to the difference in the energy of the two muscular groups of the diaphragm, but it was always considered that both groups pull the organ downward. The author disagrees and explains his new conception of the physiology of the diaphragm.

The author states that the division into area of the diaphragm the contour has been found in 7 per cent of the roentgenograms of chests in adults, but he does not indicate upon how many observations his conclusion is based. (JEROME P. PENDERGRAM, M.D.)

Basal Pleural Fluid Accumulations Resembling Elevated Diaphragm. DEAN B. JONES. *Radiol* 27 645, 506: 7

The author presents 5 cases in which fluid accumulation at the base of the lung closely simulated elevation of the diaphragm. The occurrence of a collection of fluid between the basal surface of the lung and the superior surface of the diaphragm yields a roentgenographic appearance which must be distinguished from subphrenic disease, paralysis of the diaphragm, atelectasis, eventration of the diaphragm, hernia of the diaphragm and intra pleural or intrapulmonary neoplastic disease.

In 3 of the cases a solid density practically equal to that of the liver separated the base of the lung from the gas bubble in the stomach, while ordinarily the two are separated only by the thickness of the diaphragm. In the cases of fluid in the base of the right pleural cavity small pneumoperitoneum will reveal the under surface of the diaphragm and show a thick layer of fluid between the base of the lung and the upper diaphragmatic surface. A lateral decubitus film is also of value in order to identify the diaphragm. Under normal conditions, as fluid enters the pleural space all of the free portions of the lung tend to collapse to an equal degree. The force of gravity causes the greater part of the fluid to accumulate at the base, thinning out in the axillary line. The negative pressure resulting from retractibility of the lung is the force which opposes gravity and draws the fluid upward. Without this force, the fluid would assume a "level." In the presence of basal effusion the major factor accounting for the atypical distribution is believed to be any situation which opposes the normal retractile tendency of the major lateral, anterior and posterior surfaces of the lung. In the presence of such restraining factors, only the basal surface is free to retract and this action draws the fluid upward in a cupola shape under the base of the lung. Adhesions between the visceral and parietal layers of the pleura are believed to be the major factors. Emphysema, pulmonary fibrosis, and consolidation affect retractibility of the lung and probably influence the distribution of the pleural fluid.

FRANK L. HOSNEY, M.D.

Differential Diagnosis of Retrocardiac Shadows. STANLEY S. NIMMO. *Radiology* 1948, 50: 174.

Early detection and proper evaluation of abnormal retrocardiac shadows may establish a diagnosis before the clinical signs and symptoms are present. The pericardium and the heart cast a triangular shadow on a posteroanterior roentgenogram of the chest. The heart shadow fills the entire pericardial shadow. The apparent duplication of the cardiac shadow which gives the impression of the heart visible within the pericardium is usually due to herniation of the stomach through the diaphragm, or to the rare condition of thoracic stomach with congenitally short esophagus.

A lateral roentgenogram of the chest may or may not show a definite retrocardiac opacity, but the barium meal confirms the diagnosis. The presence of multiple convex lines outlining the dome-shaped retrocardiac opacity constitutes an important diagnostic sign indicating that the stomach is in the retrocardiac region. The convex lines show the thickness of the peritoneal sac and stomach wall, which can be demonstrated by use of the double contrast method. By utilizing the gaseous properties of carbon dioxide present in ordinary soda fountain water, adequate contrast can be secured. 8 to 16 ounces of cold carbonated water is administered. This distends the stomach so that subsequent administration of barium will outline the course and displacement of the stomach. Roentgenograms are made in the positions which will best demonstrate the length and the course of the esophagus. The use of thick barium and Trendelenburg decubitus position may be of value. Megacystophagus produces widening or reduplication of the right cardiac contour and obliteration of the right cardiophrenic angle. The opacity has a slightly convex right sided border and frequently produces a uniform widening of the right half of the mediastinal shadow, with extension, sometimes, of the shadow above the clavicle. Barium will outline the esophagus. Aortic aneurysm, tortuous aorta, and the retrocardiac stomach produce left sided widening. A large esophageal diverticulum may produce a retrocardiac shadow. Its mobility differentiates it from tumors and aneurysm. Mediastinal cysts of enteric origin produce roughly spherical opacities of homogeneous density which may extend beyond the cardiac outline. These cysts occur in infancy and early childhood and may produce pulmonary compression, and occasionally may erode the ribs. Complete atelectasis of the lower lobes presents a well known characteristic triangular retrocardiac opacity which obliterates the cardiophrenic angles. Bronchiogenic cyst appears as round uniform homogeneous opacities, usually in the upper two-thirds of the mediastinum. These may be visible through the cardiac shadow. A large tuberculoma has also been reported as casting a shadow suggestive of an aneurysm. Eccrinococcus cysts are usually larger and extend beyond the cardiac outline. Tuberculoma of the spine with associated paravertebral abscess is the most common cause of abnormal rounded or fus-

PHYSICO-CHEMICAL METHODS IN SURGERY

form retrocardiac shadows in children. The typical narrowing of the intercostal spaces and the associated kyphosis make the diagnosis obvious. In adults scoliosis frequently produces duplication of either the left or the right cardiac margin. Tumors of neurogenic origin usually appear as single, sharply outlined rounded or oval nonpulsating shadows on one side of the vertebral column.

Sympathicoblastoma occurring in children may produce a round or fusiform retrocardiac shadow which may extend beyond the cardiac outline. Fibrosarcoma may produce a round retrocardiac shadow as a fusiform or globular area of opacity and may be visualized through the left half of the cardiac shadow as a fusiform or globular area of opacity and may produce duplication of the cardiac shadow. The presence of longitudinal, peripheral calcifications outlining the wall of the aneurysm and bone erosion when present are of diagnostic value. Enlargement of the aorta is easily recognized. An enlarged left atrium on slightly overpenetrated films can be visualized as a distinct chamber of the heart within the cardiac shadow.

FRANK L. HOUSEY M.D.

Hiatus Hernia S. COCHRANE SHANKS. *Brit. J. Radiol.*, 1948, 21: 53

The term hiatus hernia includes two conditions: congenital thoracic stomach and true herniation of the stomach through the esophageal hiatus. More recent work has demonstrated however that the differentiation between the two conditions is not as simple as was thought originally since the majority of the cases of short esophagus are really acquired.

The author discusses in detail the embryology and the developmental mechanism of hiatus hernia. The anatomy of the hiatus region is important. It appears that there is no cardiac sphincter in the sense of a pyloric sphincter yet some occlusive mechanism must prevent cardiac regurgitation. It is the author's opinion that three factors may enter the picture: (1) a valvelike action dependent on the obliquity of the junction of the esophagus with the stomach; (2) the diaphragmatic pinchcock which comes into effect especially when the diaphragm is in contraction during deep inspiration or when the intra-abdominal pressure is raised by abdominal muscular contraction; and (3) a physiological sphincter.

The average age of onset of herniation is from 50 to 60 years and the condition is rarely found under the age of 40. This fact alone suggests that even in the presence of a short esophagus, true congenital thoracic stomachs are rare. With increasing years many tissues lose tone and become lax. According to Schatzki the hiatus becomes widened in the elderly due to loss of fat in and around the hiatus, loss of elasticity in the latal connective tissue and stretch ing of the muscle fibers forming the hiatus. Thus in the etiology of the hiatus hernia must be sought in such an acquired defect. To this may be added the factor of increased intra-abdominal pressure, especially in obesity and pregnancy. The upward trac-

tion of the esophagus in peptic ulcer of the lower end of the esophagus and the shortening of the esophagus due to vagovagal reflexes, as, for example from distention of the gall bladder or stretching of the gastric wall also play a definite role. It is noted that obesity, gall bladder disease and duodenal ulcer figure as the most common causes of recurrent hiatus hernia.

The symptoms of hiatus hernia are very variable. About 20 per cent of all cases show no symptoms. In the others, symptoms may appear at birth or at any time during later life. They tend to increase in severity with progress of the disease and with incarceration. In the main they may be divided into two groups: (a) the gastric group such as epigastric discomfort, belching, esophageal regurgitation and vomiting; and (b) the pressure group including palpitation, anginal pain, dyspnea, syncope and hiccough.

Harrington classifies hiatus hernia as follows: (a) congenital partial thoracic stomach with short esophagus; and (b) acquired hiatus hernia. This latter is subdivided into type I (when the esophagus is of normal length and part of the gastric fundus is herniated into the posterior mediastinum also called paroesophageal hernia), type II (in which a larger part of the stomach herniates carrying with it the esophagus which is not noticeably shortened and enters the stomach at its side), type III (in which the esophagus enters the stomach at its highest point) and type IV (in which the stomach protrudes like a funnel through the diaphragm and the esophagus enters at its highest point). There is no true hernial sac in this type.

The diagnosis of hiatus hernia is made by roentgen examination or esophagoscopy. The chief value of the latter is to check the length of the esophagus and the presence of esophageal ulcers or strictures. From the point of view of roentgen study the author distinguishes between the reducible or sliding hernia, and the irreducible or incarcerated hernia. The sliding type may easily be missed unless one sets out specifically to look for it. To detect it, examination in the supine oblique supine or Trendelenburg position is necessary with the patient's stomach partly filled with barium. When the patient is in the most satisfactory position a further bolus of the opaque medium is given and watched as it passes down the esophagus. If nothing abnormal is seen the valsalva procedure is used. A sliding hernia can be mistaken for two other conditions: a large phrenic ampulla and a mild degree of congenital short esophagus with a small contracted gastric fundus. The differentiating signs are discussed. Sooner or later most hiatus hernias become irreducible. The article is well illustrated with roentgenograms and some diagrams.

T. LEUCUTIA M.D.

The Treatment of Keloids by Irradiation and Electro-surgery GEORGE E. FRAHLER and GEORGE P. KEEFER. *Am. J. Roent.*, 1948, 50: 378.

Keloids or hypertrophied scars are difficult to treat. It requires great patience on the part of both

the patient and the physician. So far as is known roentgen rays and radium are the only two agents which will arrest the disease or cause it to disappear. If these agents are used thoroughly when the scar begins to hypertrophy there will probably be no need of combining excision or electrosurgery with the radiotherapy.

Electrodesiccation or electrosurgery are used to reduce the hypertrophied tissue to skin level prior to roentgen irradiation.

Treatment is given with superficial or 125 kilovolt therapy. For postoperative irradiation, 50 to 100 per cent of an erythema dose is given. If the wound is healing by granulation, 50 per cent of erythema dose is given in 2 weeks and this dose can be repeated in from 2 to 4 weeks if any tendency toward hypertrophy persists. Older flattened keloids are treated with similar increments at 4 to 6 week intervals. Thicker old keloids are treated with small increments at weekly intervals. The purpose of this method of treatment is to bring about change without prominent atrophy or telangiectasis.

Flat radium application is filtered to eliminate the beta rays can also be used effectively.

If the keloids or hypertrophied scars are very dense it is usually best to destroy the lesions to the level of the skin by electrodesiccation or to remove them with scalpel or electrosurgery. The healing then must be carefully controlled by irradiation generally by roentgen therapy.

JOSEPH P. TOKSOLA, M.D.

Röntgenological Aspect of Sarcoidosis. ALFRED J. ACKERMAN. *Am J Roentg* 948, 50 3 B.

The author presents a discussion of the clinical aspects of sarcoidosis, particularly with regard to the pulmonary manifestations of the condition as seen in the roentgenogram.

The great individual differences in the distribution, extent, and character of the lesions are believed to be due to the evolutionary stages of the disease. Early lesions may not be seen because of the frequently asymptomatic course and sarcoidosis may be well advanced when it is first discovered. Extended observation will reveal the fluctuating course of the disease. New lesions may appear at any time and older ones may change or regress.

Frequently all manifestations, including enlargement of the mediastinal nodes, millary infiltration, areas of fibrosis and coalescent areas of patchy infiltration may be observed at one time in the same patient.

Enlargement of mediastinal nodes is quite characteristic, frequently with increase in mediastinal dimensions. This increase is usually bilateral and symmetrical, but may exist on one side only. The size ranges from mere hilar enlargement to large tumor masses extending into the lung fields. Pressure symptoms are usually lacking. Spontaneous complete regression of these masses may occur. In spite of the extensive evidence of disease symptoms are often absent.

The pulmonary manifestations of sarcoidosis are not pathognomonic per se. Changes are rarely uniform and no form of infiltration can be attributed to a specific stage of the disease. The distribution can be local or rather extensive in any phase. Single aspects of infiltration may occur without node involvement in phases of the disease.

Diffusely disseminated infiltrates consist of discrete small nodular foci resembling the nodules of millary tuberculosis. The distribution of such lesions may take any form. Diffuse or localized infiltrations of a linear or strandlike character seem to follow the distribution of the vascular pattern and are seen as prominent root trunks. Coalescent patchy densities are usually seen with widespread peribronchial-perivascular and nodular infiltrations.

The various types of pulmonary lesions represent only manifestations of different stages of evolution. A complete absorption of some areas of infiltration is seen almost invariably in cases remaining under long observation.

Frequently the myocardium and pericardium are invaded by sarcoid resulting in arrhythmias, conduction defects, cardiac enlargement, and right cardiac failure.

Skeletal changes occur in 20 per cent of cases of sarcoidosis. The author did not observe such changes in his series of 19 cases. The bone changes may be of the punched-out type or of the diffuse variety.

Four cases are presented in detail. The author concludes that the diagnosis may be established only by biopsy and that the prognosis in pulmonary sarcoid must be guarded. HORACE G. BUTLER, M.D.

Tissue-Dosage in Roentgentherapy of Mammary Cancer. BLAVARCE LEXA. *Acta radiol* Stockh, 947 38 583.

There is still no agreement as to the exact amount of roentgen therapy required (when used alone or combined with mastectomy) for preoperative or postoperative treatment of mammary cancer. Results vary chiefly with the extent of the cancer prior to irradiation and with the dosage delivered to the tumor.

Postoperative irradiation is given in the hope of arresting clinically nonrecognizable foci in the mastectomy area, axillary tissues, supraclavicular and infraclavicular lymph nodes, or in the lymph nodes of the anterior mediastinal or internal mammary chain. Progressive growth of distant metastases, if present when therapy is begun, is not influenced by any local improvement in the irradiated areas.

Reference is made to the experience of McWhirter (*Edinburgh M J* 1942 50 103-107) which suggests that important growth restraint for at least 3 years may be obtained by a tissue dose of from 3,500 to 4,500 roentgens given in 4 weeks.

Between 1933 and 1937, preoperative irradiation was given to 38 patients. The breast and axilla received up to, but not exceeding, a 4,500 roentgen tumor dose in 6 to 8 weeks and mastectomy was done from a few days to more than one year later.

PHYSICO-CHEMICAL METHODS IN SURGERY

In 9 specimens with biopsy and mastectomy, comparisons were made by means of biopsy and mastectomy and Stout found cancer cells could be demonstrated in every one.

Since 1938 only inoperable cases fitting the Haagenson-Stout classification have been treated. Fifteen patients received less than 5,500 and 8,000 roentgens to the breast. The axillae were cross fired through anterior posterior and direct fields with doses varying between 2,500 and 5,000 roentgens in air.

Of the 32 patients receiving a tumor dose of between 5,500 and 8,000 roentgens, 11 are now alive and free from clinical evidence of cancer from 7 to 9 years after their irradiation therapy. No claim is made that they are cured. Cancer cells may still persist within a dense sclerotic stroma.

In view of these findings radical mastectomy is to be preferred in all operable cancers of the breast. In inoperable cases only roentgen therapy should be used.

J. P. TOMSULA, M.D.

Studies on the Effects of Radiation upon the Mobile Visible Lipids in Human Blood. KAI SIZALLA.
Ann. med. exp. biol. fenn., 1947 25 Supp. 1

An attempt was made to inquire into the effects of roentgen or radium treatment on the mobile visible blood lipids before the lipids were deposited in the liver or in other bodily organs. Subjects of the investigation were 32 individuals who were in the same hospital (Central Institute for Radiation Therapy Helsinki) and who presented the same external conditions during the whole observation and treatment period.

As a method of investigation, no chemical quantitative determinations were chosen, but in all persons the amount of chylomicron in the blood was counted every half hour. Though the chemical character of chylomicrons is not finally solved, there are now solid proofs of the truth of the assumption that at least the majority of them are formed of lipids. The amount of chylomicrons was always in direct

proportion to the amount of fat taken. The examination of the blood was always performed by the same person with the same instruments.

It was found that roentgen as well as radium irradiation regularly caused changes in the amount and in the metabolism of mobile visible blood lipids of both healthy and tumor-bearing individuals. Further, it was found that if changes were to be attained, irradiation must be given in certain relation to the fatty food taken. It appeared also that when certain regions of the body were irradiated, such as the lower abdomen, the liver, the chest and especially organs in which the tumors were in the necrotic phase, the changes were most considerable.

In seeking an explanation to the phenomena described, the histamine theory was also used as a basis in this work. Histamine acid phosphate was injected intramuscularly to the test individuals. It appeared that the histamine administration when performed at a suitable period effected marked changes in the lipid amount and in the lipid metabolism in the blood of both healthy and tumor-bearing individuals.

In those persons who exhibited symptoms indicating irradiation sickness, the changes were particularly severe.

The author assumes that the decrease or disappearance of the mobile visible blood lipids may partly be an effect of the hemoconcentration of the blood, owing to the probably increased permeability of the capillaries and that it is caused by irradiation or the administration of histamine. At the same time the blood plasma passes through the injured capillary walls, chylomicrons may also pass with the plasma. Particularly striking was the fact that after irradiation, as well as after administration of histamine and the effect usually appeared comparatively soon. The effects of the histamine sometimes remained for a period of several hours.

The effects of irradiation or histamine (or both) are hardly direct as regards the liver.

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

The Control of Body Water Balance. CHAMBERLAIN
BROOKS. *Med. J. Australia*, 1948, 1: 87

Many phases of the physiology of the control of body water balance are presented. Water is the chief body component: it comprises 70 per cent of man's total weight. It is the medium for the exchange and metabolism of many organic solutes and the solvent essential to chemical reactions upon which life depends. Extracellular fluid constitutes 20 per cent of the body weight and consists of the intravascular fluid approximating 5 per cent of this, while the interstitial fluid makes up the other 15 per cent. The water contained within the cells as a component of protoplasm is bound more firmly to its location than the extracellular fluid and constitutes about 50 per cent of the total body weight. The volume of water within these compartments may be ascertained at any one time by the use of blue dye T 1824, sulfoeyanate, radioactive sodium, sucrose, urea, or deuterium oxide. The type of substance dissolved in or held by the water of these three compartments differs, but that is because of the selective permeability of membranes and other factors. Intracellular fluid contains potassium as its chief cation, and phosphate and protein as the main anions, while extracellular fluid contains chiefly sodium, chloride, and bicarbonate. The movement of various substances such as salts, urea, and proteins cause water to move along with them, and salt depletion or salt excess greatly alters the water volume content of the extracellular and intracellular compartments.

Man can probably withstand to 15 per cent reduction of his total body water before collapsing, but from 1 to 4 per cent reduction of body weight has measurable consequences such as increased heart rate, elevation of deep body temperature, diminished cardiac output, exhaustion and, finally, mental instability and depression. The blood loses two or three times as much of its volume as does the body as a whole. In mammals the only natural route of water gain from outside is through the alimentary tract and water ingested into an empty tract is absorbed within 40 to 60 minutes. Hypophysectomy prolongs total absorption by at least 50 per cent. Man averages approximately 5,000 milliliters of fluid—water, milk, tea, or coffee—daily but under desert conditions intakes up to 15 liters daily have been reported. Meat affords man 75 per cent of its weight in water, and vegetables, 50 per cent. Normally the individual obtains about 1,000 milliliters of water in this way. Finally, he manufactures water in the process of metabolizing food materials. In burning 100 grams of protein 31 grams of water are obtained, and every 100 grams of fat yields 107 grams of water while 100 grams of carbohydrate

yields about 60 grams of water. The total gain daily through normal metabolism yields about 300 milliliters.

Water is lost from the body in several ways. Insensible loss or evaporation loss averages normally 900 milliliters daily but under conditions of dry heat may approximate 1,500 milliliters. Respiratory loss approximates 400 milliliters. In hot, moist atmospheres over 3 liters of sweat may be secreted per hour. Under desert conditions men may lose as much as 15 liters of fluid in sweat each day. As men become acclimatized to heat they lose more sweat than they did before. The maximal rate of sweating without water can be attained within 20 minutes, but after 2 hours of maximal sweating the rate declines and at 6 hours the rate is so slow that cooling fails. The normal urine output is about 1,400 milliliters but this varies greatly with water requirements.

In conclusion, the author discusses the physiology associated with diabetes insipidus. Its production is mediated through interruption or injury to the hypothalamohypophyseal system with resultant deficiency of the antidiuretic hormone.

EDMUND A. GORVETT, M.D.

The Functional Pathology of Experimental Immersion Foot. KURT LAMKE, DAVID WENGER, and LOUIS J. BORD. *Am. Heart J.* 1948, 35: 38

The authors investigated the functional pathology of trenchfoot by exposing the legs of rabbits to water at a temperature of from 3 to 5° C. for 3 or 4 days. The temperature of the exposed limbs rapidly dropped but leveled off at about 15° C. Some circulation persisted throughout, as shown by fluorescein injection and by the appearance of edema (this can only appear in the presence of a positive filtration pressure). Upon removal from the water the legs showed severe edema and a flaccid paralysis and soon became very hyperemic. The edema subsided in 1 day but the loss of muscular power persisted for from 4 to 1 week in most animals. There was no gangrene except in areas of superimposed trauma or infection. Histologic sections showed no vascular thrombi, which are so characteristic of frostbite. Lesions seemed confined to muscle and predominantly to the nerve tissue, in which severe degenerative changes were found for weeks following the exposure. The temperature of blood from a leg during exposure was almost the same as the internal temperature of the leg. At a temperature of from 6° to 8° C., the oxygen dissociation of the blood is very low and in fact, venous blood from the legs during exposure was observed to be a bright red.

Some of the animals showed a marked decrease of body temperature during the exposure. When this fell to between 34 and 36° C., deep depression of the S-T segments in all leads of the electrocardiograph was seen: this was followed by an elevation of the

S-T segment with inverted T waves as are seen in myocardial infarctions (anoxia of the myocardium?) Morphologic examination of the hearts in these animals has thus far failed to show any specific lesion.

The authors conclude that the lesions of experimental trenchfoot are different from those of frost bite in that the former are characterized by muscular and neural injury due to tissue anoxia secondary to decreased circulation and poor oxygen dissociation, whereas the latter are the result of multiple vascular thrombi and total failure of the local circulation with resultant gangrene. Frostbite is due to sudden extreme cold and trenchfoot to prolonged lesser cold but the two may overlap. JAMES WEAVER, M.D.

The Effect of Local Compression upon Blood Flow in the Extremities of Man. MEYER H. HALPERIN, CARL K. FRIEDLAND, and ROBERT W. WILKINS. *Am Heart J.*, 1948, 35: 221.

When 5 individuals were subjected to increases of pressure on one hand by a plethysmograph there was an average reduction in skin temperature of the fingers of about 1 degree centigrade as compared with the control hand with a pressure of 30 mm. of mercury. A definite reduction was also elicited by 20 mm. of pressure. In 2 subjects a mean drop of 4.8 degrees centigrade between the two hands was effected by subjecting one hand to 50 mm. of pressure.

Blood flow through an organ may be determined from its oxygen uptake. In 5 subjects there was an average decrease in the oxygen content of venous blood from the antecubital fossa when pressures of 20 and 30 mm. of mercury were applied to the forearm with the circulation of the hand shut off throughout such as would signify decreases of blood flow of 25 and 34 per cent respectively.

When measurement of the absolute blood flow was made by recording on a kymograph the volume of the forearm with a water plethysmograph (under an unvoidable initial pressure of 8 3/4 centimeters of water) with the hand circulation again occluded completely by a cuff about the wrist, it was found that a decrease of 10 per cent occurred in the flow of blood through the forearm when a pressure of 10 mm. of mercury was applied by another cuff above the plethysmograph. Pressures of 20 and 30 mm. reduced the flow 24 per cent and 40 per cent respectively.

These experiments show the importance of small increments of pressure (as small as 10 mm. of mercury) to the reduction of peripheral blood flow such as might be induced by snug clothing, bandages, splints, or even the weight of bed clothes on bony prominences. These results assume particular significance with patients who already suffer from peripheral vascular disease. JAMES WEAVER, M.D.

Pentothal Sodium and Serotherapy in the Treatment of Tetanus (Pentotal sodium e sieroterapia nel trattamento del tetano). G. CADILLI. *Minerva med.* Tor. 1948, 39: 12.

The combination of serum therapy with the employment of sedatives was introduced into the treat-

ment of tetanus by Dufour and Duhamel in 1925, with the idea that the sedative effect changes the cellular metabolism and thus facilitates the action of antitoxin on the tetanus toxin. Numerous observations showed that sedatives liberate in vitro the tetanus toxin from the halo substance. However, in vivo the administration of the combination of serum and ether, chloroform, or ethyl chloride, respectively did not fulfill the expectation.

The author studied the effect of pentothal sodium on tetanus in rabbits. He employed 40 mgm. of sodium pentothal per kilogram of body weight in a 2.5 per cent solution. This dose was given intravenously within from 20 to 30 minutes. The author found that the rabbits survived the lethal dose of tetanus toxin if sodium pentothal was administered within 45 hours after the injection. The total dose of sodium pentothal ranged from 112 to 256 mgm. The amount of serum administered to rabbits was 1,500 units in one group and 10,000 units in the second group. The serum was administered between 18 and 87 hours after the infection.

The good results suggest a similar treatment in man. JOSEPH K. NARAT, M.D.

Superficial Total Lymphangiectomy. Surgical Treatment of Elephantiasis (La lymphangectomie superficielle totale. Traitement chirurgical de l'elephantiasis). M. SERVELLE. *Rev. chir. Par.* 1947, 66: 394.

Since at the beginning of this century it was realized that elephantiasis is due to lymphostasis, various surgical methods have been devised for treatment. Most of these operations have for their purpose the drainage of the stagnating lymph. The section of long silk strands or rubber tubes in the subcutaneous tissue from the ankle to the anterior abdominal wall was tried without much success. Other surgeons resected a wide strip of the superficial aponeurosis and edematous tissue in the attempt to drain the edema toward the deep lymphatic vessels. Furthermore lumbar and perilemoral sympathectomy has been done by several men. All of these methods proved unsuccessful in curing the lymphostasis and ensuing elephantiasis.

The author has devised a new method for the treatment of elephantiasis which he calls "superficial total lymphangiectomy" and he reports a series of 25 cases (19 of the leg, 1 of the arm, and 5 of the penis and scrotum) in which this operation led to excellent results.

Lymphography and fluoroscopy of the lymphatics proved very helpful in understanding the mechanism and pathogenesis of elephantiasis and in determining the extent and site of the dilated lymph vessels. A syringe is inserted in a dilated lymph vessel and a large amount of lymph up to 1,500 c.c. in some cases, is drawn and replaced by the contrast medium which is injected through the same needle. In true elephantiasis the superficial lymphatics show tremendous dilatation and hypertrophy often having the caliber of a finger. Due to this extreme dilatation

the valves of the vessels become incompetent, and the lymph circulation normally somewhat slower than the venous circulation, stops altogether.

As to the etiology most case histories reveal that the trouble started after some minor infected skin abrasion, insect bite, or similar lesion which caused an adenitis of the regional lymph nodes (Inguinal iliac). Very gradually fibrosis of the lymph nodes leads to obstruction of the lymphatics and blocks the circulation.

Before a decision is made regarding the kind of management required, it should be verified whether the case is a true elephantiasis, i.e., a lymphostasis or an edema caused by a phlebotic process. Therefore in all doubtful cases a venography should be done in addition to the lymphography.

In true elephantiasis, the treatment of choice is total resection of all the lymphatic tissue involved and of the superficial aponeurosis. The operation is done in two stages: (1) incision from the major trochanter down to the external malleolus, the epidermis and dermis being dissected from the underlying tissue back to the midline anteriorly and posteriorly and the entire subcutaneous tissue including the superficial aponeurosis is removed in one block, and (2) after 3 months, the same operation is done at the medial aspect of the leg.

This is a formidable operation which necessitates blood transfusions before and after surgery. However, in 30 such operations the author has obtained excellent results. W. VAN M. GELDER, M.D.

The Calcified Halo: Diagnostic Sign of Hydatid Cysts of the Liver and the Operative Approach to Large Cysts of the Superior and Posterior Surfaces of the Liver (El halo calcico. Signo de diagnóstico en los quistes hidatídicos del hígado y sobre la vía operatoria de abordaje en los grandes quistes de la cara superior y posterior del hígado). D. FRAT L. C. RERA and E. ZERROWI. 4. *Pac med Mexico* 947 5 536.

In the roentgenograms of some patients with hydatid cyst of the liver there is seen evidence of spherical tumors with well demarcated outlines. These have been named calcified halos. This difference in density which totally surrounds the cyst or at times only partially is due to an accumulation of calcified material in the wall of the cyst.

The first films of hepatic cysts with a calcified halo which were observed were classified by the radiologist as calcified cysts of the liver. It was finally shown at operation that these cysts were not actually calcified as the capsules were soft and malleable, but they contained a high concentration of calcium in their walls. An additional sign of extreme importance in cysts of the posteroinferior aspect of the liver is downward displacement of the kidney demonstrated by intravenous pyelography.

The anterior or posterior parapleural approach is the surgical procedure of choice for cysts of the superior or posterior surfaces of the liver. This may be carried out under general or local anesthesia.

In those cases in which there are cysts of the superior surface of the liver which may not be approached via the abdomen the operative approach is made through the anterior thorax with resection of the seventh, eighth, or ninth rib after the anterosuperior position of the cyst is confirmed by a profile roentgen film.

Choice of the rib to be resected depends upon the actual location of the cyst. This resection permits elevation of the pleural sac. The diaphragm and peritoneum are incised and the anterosuperior surface of the liver is exposed. By this method an adequate operative field is obtained.

With large cysts of the posteroinferior surfaces of the liver the parapleural approach may be used to advantage. With the patient in the left lateral decubitus position a posterior thoracolumbar incision is made. The twelfth or eleventh rib, usually the latter is resected. The roof of the inferior pleural sac is raised, the diaphragm incised, and the liver exposed.

The case histories and operative notes of 9 patients are presented. Three of the patients had hydatid cysts of the posterior surface of the liver. One had an amebic abscess. All of these patients were operated upon through the posterior parapleural approach. Five of the patients had hydatid cysts of the superior surface of the liver and these were operated upon through the anterior parapleural approach.

HAROLD W. BICKNELL, M.D.

Myeloplasmoma with Malignant Transformation (Tumor a mieloplasmal en transformación maligna). FABIO F. BIANCHI and GIOVANNI BELLESCI. *Radiol. med Milano*, 943, 31 9.

A case of myeloplasmoma with malignant transformation in a 37 year old female is described by the authors.

At 18 years of age this patient had an injury to the second toe developing a hematoma which finally disappeared.

Seven years after injury and during the first of her 4 pregnancies she observed a tumor on the dorsal surface of the first phalanx of the second toe. Pain was present throughout her pregnancies and subsided after delivery only to become worse with each succeeding pregnancy, the tumor finally reaching the size of a walnut. The pain became intense after her fourth delivery. Passive movements were possible and active movements were reduced.

The tumor became adherent to the skin which was of a bluish color. It was fusiform in shape and had a hard consistency.

Roentgenography showed without doubt that the tumor was malignant because it broke through the osseous tissue and invaded the soft tissue. No signs of periosteal reaction were observed.

A disarticulation of the second toe was done.

On section the tumor was found to be brownish red with clear brown zones toward the center of the mass. The base of the tumor was situated over the bone.

Microscopically the connective tissue was dense having a few nuclei however the part near the epidermis contained multinucleated cells with little protoplasm. These cells contained from 5 to 10 nuclei of dense chromatin and of equal size. The cells stained strongly acidophilic however, some were weakly basophilic, and still others were chromophilic.

The author calls particular attention to the trauma and pregnancy relationship of the tumor, and to the rarity and difficulty of the clinicoradiologicohistological diagnosis. This condition had to be differentiated from tuberculosis syphilis solitary cyst of the bone, Bruno tumor chondroma, giant-cell tumor, and polymorphous giant-cell sarcoma fibrosarcoma and reticulosarcoma.

ARTHUR F. CIPOLLA, M.D.

GENERAL BACTERIAL, PROTOZOAN AND PARASITIC INFECTIONS

Nose and Skin Carriage of Staphylococcus Aureus in Patients Receiving Penicillin BRENDA MOSS, J. R. SQUIRE, ELIZABETH TOPLAY, and C. M. JOHNSON *Lancet, Lond., 1948, 1, 310.*

The frequent isolation of the Staphylococcus aureus (coagulase-positive Staphylococcus) in pure culture from many purulent lesions including osteomyelitis is strong evidence of the pathogenicity of this organism to man. Scrabbling large and varying samples of the adult population has repeatedly revealed a high incidence of this organism in the nose and a high incidence of this organism isolated from the nose and skin of one person usually shows them to be of the same type. This suggests the hypothesis that the staphylococci found on normal skin are usually derived from the nose probably by direct contact.

The authors gave penicillin experimentally through the nose to reduce the carrying of the Staphylococcus aureus and noted the associated findings on the skin. The normal skin site used was the back of the wrist. Penicillin cream or spray in a total of from 50,000 to 100,000 units over 10 days reduced detectable nasal carrying of the Staphylococcus aureus in a group of 21 persistent carriers. However systemic administration of penicillin in a daily dosage of 100,000 units failed to influence nose or skin carrying of the Staphylococcus aureus in 15 patients. This failure may be explained on the hypothesis that the site of the Staphylococcus aureus on the epithelium of the skin and nasal vestibule is not reached by any transudate from the capillary blood. In support of this it has been shown that neither human sweat nor cat's tears contain any demonstrable penicillin after systemic injection. The reduction of the nasal carrying of Staphylococcus aureus following the intranasal use of penicillin was associated with a significant fall in the number of organisms on the normal skin in 8 of 13 persistent nasal carriers. This suggests that the nose may be the predominant source of this organism on the wrist.

In the 5 patients in whom the intranasal use of penicillin was a failure, the close association between

nose and skin carrying could be due to colonization of either or both sites. It is well known that Staphylococcus aureus can always be isolated from healed as well as from healing wounds and burns. There also are persons with intact skin who carry this organism with an abnormal heaviness and persistence in a multiplicity of sites. It is clear that the incidence and significance of Staphylococcus aureus skin colonization require further investigation.

A much higher incidence of the Staphylococcus aureus was found in the nasal vestibule than in the middle fossa of the nose. This suggests that the squamous epithelium of the vestibule is the primary site of colonization. It is suggested that the therapeutic or prophylactic value of intranasal administration of penicillin be evaluated for the prevention of staphylococcal contamination of skin surfaces in burns and other skin lesions.

EDMUND A. GORVETT, M.D.

The Bactericidal Action of Streptomycin LAWRENCE P. GARROD *Brit. M. J., 1948, 1, 383*

Insofar as the action of a chemotherapeutic agent is bactericidal that action must be influenced by the various factors such as concentration, temperature, medium, and inoculum size, which are known to affect chemical disinfection generally. Experiments were undertaken to provide information on these points with regard to streptomycin. The organism used was the Staphylococcus aureus (Oxford H strain) the inoculum being derived from a 24 hour culture in ox heart-extract peptone broth. The basis of the test mixture was usually the same broth to which was added streptomycin and such an amount of culture as to give an initial viable count of about 50,000,000 per milliliter.

Viable counts were made at intervals. Curves showing the fall in the viable count of the Staphylococcus aureus are given with four different concentrations of streptomycin. An original population of 95,000,000 per milliliter was entirely extinguished by 2,000 µg per milliliter in 8 hours by 50 or 100 µg per milliliter in 4 hours and by 2,000 µg per milliliter in 2 hours. With 2,000 µg per milliliter a rather large inoculum which was only partially extinguished with 200 µg per milliliter was completely extinguished. It appears that the death rate varies with the concentration of the drug and the action therefore differs radically from that of penicillin which is not accelerated by increase in concentration above a certain level.

All bactericidal action is accelerated by increase in temperature and streptomycin makes no exception to this rule. The viable count decreased as the temperature increased. The effects of streptomycin on the death rate of different species were notably the same when the Bacterium coli and the Streptococcus pyogenes were used as when the Staphylococcus aureus was used under the same conditions. In order to determine the effect of other media, broth culture of the Staphylococcus aureus was thoroughly washed (centrifuged 3 times and resuspended

saline solution) and the suspension was added to defibrinated blood or serum containing 2000g of streptomycin per milliliter. It was found that the rate of fall in the viable count approximated closely that observed in the broth. In urine (sterilized by filtration and adjusted to pH 7.4) the effect was similar but less rapid. On the other hand washed culture added to saline solution containing 2000g of streptomycin per milliliter was completely unaffected; the viable count as in the saline control containing no streptomycin remained almost stationary throughout the whole experiment. With higher concentrations of streptomycin in a nonnutrient medium, it appears that very high concentrations of streptomycin are incompletely and irregularly bactericidal. In its dependence on a nutrient medium for rapid bactericidal action streptomycin resembles penicillin, but there is a striking difference in their effects. The effect of penicillin becomes evident only after a lapse of time amounting to about one hour while that of streptomycin is immediate—under favorable conditions it begins within one minute and may be far advanced in 10 minutes. No other bactericidal agent having so rapid an effect is so dependent on a nutrient medium for its efficacy. This peculiar behavior will have to be taken into account in any hy-

pothesis about the mode of action of streptomycin. That the size of the inoculum affects the concentration of streptomycin required to inhibit growth was shown. Tests revealed that the absolute concentration of streptomycin was not the determining factor. It is the relation between that concentration and the number of bacteria. It appears that a given concentration of streptomycin can kill only a population of a certain density; if more are present some will survive.

The fact that higher concentrations of streptomycin are more rapidly bactericidal has an important bearing on treatment. Streptomycin, like penicillin, is excreted in the urine where it attains a high concentration. If its effect in vivo parallels that described in vitro susceptible bacteria should disappear rapidly from the urine soon after excretion has begun. After 6, 8 or 12 hours if treatment is going to be successful the urine is completely sterile. If treatment is to fail specimens continue to yield counts of a few hundreds or thousands per milliliter until the second day when there is a sharp rise and the organism is found to be already much more resistant. It seems as if the issue is settled one way or the other within 24 hours or less.

SURGICAL PROCEDURES EMPLOYED AND ANATOMICAL VARIATIONS ENCOUNTERED IN THE TREATMENT OF CONGENITAL PULMONIC STENOSIS

ALFRED BLALOCK, M.D. F.A.C.S., Baltimore, Maryland

THROUGH the generosity of the Nu Sigma Fraternity at Tulane University it is my good fortune to be invited to deliver the first Rudolph Matas Lecture. I regard this opportunity as a great privilege imperfectly as I shall be able to meet its obligations for the friendship and leadership of Dr. Matas have been for me as well as for surgeons throughout the world a dear possession and a strong influence. I take delight in the thought that the late Professor Halsted would be pleased that one of his pupils should inaugurate a lectureship which hon-

Rudolph Matas

ors the name of the close friend for whom he had the greatest admiration. Because they were bound together by various ties, the visits of Dr. Matas to Baltimore were frequent. It is to be feared that as medical students we failed to appreciate fully the high value of the clinics conducted by this distinguished visitor on endoaneurysmorrhaphy, on methods for determining and increasing the collateral circulation in the presence of aneurysm, on the use of metal bands in the treatment of aneurysm, and on the causes of elephantiasis, all problems in which he and Dr. Halsted were deeply interested. It

may be of significance that one of the students present at these clinics, Dr. Arthur Blakemore, has made what is probably the most important contribution to the treatment of aneurysm since the work of Dr. Matas. The death of Dr. Halsted in 1922 ended a beautiful

The first Rudolph Matas Lecture established by Beta Iota Chapter, Nu Sigma Nu, delivered at New Orleans on January 8, 1948.

From the Department of Surgery of The Johns Hopkins University and The Johns Hopkins Hospital.

Aided by a gift from the Robert Garrett Fund for the Surgical Treatment of Children and the Carolyn Rose Strauss Foundation, Inc. grant for Diagnosis and Treatment of Congenital Cardiovascular Defects.

Fig. 4. Pure pulmonary stenosis, a relatively rare lesion in which the stenosis is usually in the pulmonary valve. Since there is not an interventricular defect and the aorta does not receive mixed venous blood, cyanosis is not a prominent feature. Patients with pure pulmonic stenosis would not be greatly benefited by the creation of an artificial ductus arteriosus.

malities which may be treated by operative means is that in which there is an inadequate pulmonary blood flow and in which mixed venous blood enters the arterial circulation. The most frequently encountered condition of this type is the tetralogy of Fallot in which there is pulmonic stenosis or atresia, an interventricular septal defect, an aorta which overrides the septal defect and receives blood from both ventricles, and right ventricular hypertrophy. Preoperative and postoperative photographs of a child with this condition are presented in Figures 1 and 2 (frontspective). It is estimated that approximately 70 per cent of patients 2 years of age and over who are cyanotic on the basis of congenital heart disease have this combination of defects. A diagram is given in Figure 3

Fig. 5. Showing the alteration in the circulation which results following the creation of an artificial ductus arteriosus in the treatment of the tetralogy of Fallot. The illustration shows an anastomosis between the proximal end of the subclavian artery and the side of the right pulmonary artery which allows the shunted blood to pass to the right or the left lung. The quantity of inadequately oxygenated blood which is exposed to the oxygen in the lungs is greatly increased. Fortunately the pressure in the aorta and its branches is high, that in the pulmonary artery is low and a large quantity of blood passes through an opening of moderate size. One may use one of the large branches of the arch of the aorta or the aorta itself for the anastomosis.

Since the pulmonic stenosis is the major defect in the tetralogy of Fallot, I wish to emphasize the point that the cyanosis is due primarily to the fact that there is an interventricular defect with an overriding aorta which receives mixed venous blood from the right ventricle as well as oxygenated blood from the left ventricle. The severity of the cyanosis depends in addition to other conditions upon the degree of the pulmonic stenosis and the degree of overriding of the aorta. It is known that at least 5 grams of reduced hemoglobin per 100 cubic centimeters of circulating blood are necessary in order to produce obvious cyanosis. In pure pulmonic stenosis in which there is no communication between the two

Fig. 6. This figure and the succeeding seven figures show the steps of an anastomosis between the proximal end of the right subclavian branch of the innominate artery and the side of the right pulmonary artery. This is the procedure which prefer in most of the patients in the age group from two years to thirteen years. The opposite side is used if the aorta descends on the right instead of the left. The insert at the top left shows the position of the patient on the operating table. The patient is lying on his back with the right side slightly elevated. The incision in the pleura is usually in the second interspace. The larger drawing shows the contents of the upper part of the right pleural cavity. The Artery v is to be doubly ligated and divided. The patient's head is to the reader's left.

sides of the heart cyanosis is minimal or absent. Dyspnea and disability may be extreme depending upon the degree of the stenosis. A diagram of pure pulmonic stenosis is given in Figure 4. Since in pure pulmonic stenosis the blood which passes through the lungs is properly oxygenated and since the aorta does not usually receive mixed venous blood the creation of an anastomosis between the greater and lesser circulations would not result in dramatic improvement. In contrast to pure pulmonic stenosis in the tetralogy of Fallot in which there is an inadequate pulmonary blood flow due to pulmonic stenosis or atresia, it is evident that there is also an interventricular defect with an overriding aorta which results in the passage of mixed venous blood as well as arterial blood into the aorta and that this combination of defects results in cyanosis and dis-

ability. Under such circumstances, if some of the inadequately oxygenated blood in the aorta were allowed to pass through the lungs as a result of the creation of an artificial ductus arteriosus this shunted blood would take up oxygen and a diminution in the cyanosis would result. The general alterations in the circulation that occur as a result of such an operation (4) are illustrated in Figure 5.

Patients with pulmonic stenosis or atresia in whom some mixed venous blood enters the aorta should be benefited by the creation of an artificial ductus arteriosus. Among the conditions falling into this category are the tetralogy of Fallot with pulmonic stenosis or atresia, nonfunctioning right ventricle with functional pulmonic stenosis or atresia, single ventricle with pulmonic stenosis or atresia, truncus arteriosus with circulation to the lungs through

Fig. 7 Showing the right pulmonary artery. It lies superior and slightly posterior to the superior pulmonary vein. Identification of these two structures may be difficult when the pulmonary artery is small and when there are extensive collateral arterial vessels. A long length of the right pulmonary artery is dissected free of the adjacent tissues and the point of division of the artery is exposed.

bronchial arteries and with a rudimentary pulmonary artery with which an anastomosis can be performed transposition of the aorta and pulmonary artery in association with a large interventricular defect and pulmonic stenosis and numerous variations in these defects. It is possible that patients with a normal or increased pulmonary blood flow in association with an interventricular septal defect and an overriding aorta (as in the Eisenmenger complex) may be improved somewhat by the creation of an artificial ductus arteriosus. This point has not been determined. Certainly the primary indication for the operation is an inadequate flow of blood to the lungs and an interventricular defect with an overriding aorta.

Clinical laboratory and radiological evidences of the presence of pulmonic stenosis or atresia have been described in detail by Dr. Taussig and by others. Included among the important positive points in the typical case are cyanosis, dyspnea, poor exercise toler-

ance, squatting, low arterial oxygen saturation, polycythemia, a systolic murmur in the pulmonary area, a concavity in the pulmonary area on x-ray examination, a clear pulmonary window in the left anterior oblique position, diminished hilar shadows, and absence of pulsations at the hili of the lungs on fluoroscopic examination. A useful laboratory procedure described recently by Dr. Bing and his associates is the finding that the oxygen consumption per liters of ventilation decreases with exercise in patients with the tetralogy of Fallot, whereas it increases in those without pulmonic stenosis. A history of squatting following exertion is given by the great majority of patients with inadequate pulmonary blood flow. Many of the patients literally sit upon their heels for extended periods. In general, radiological methods are of much greater aid in diagnosis than is physical examination, although both are important. It is obvious that the severity of cyanosis and disability will depend to a considerable extent on the degree of

Fig. 8. Showing the exposure of the innominate artery and its branches, the right subclavia and the right common carotid artery. Exposure is accomplished by dissecting posterior to the superior vena cava. The innominate artery usually rises from the aorta slightly to the left of the trachea. These vessels are dissected free of the adjacent tissues and adequate mobilization obtained. If thyroidea ima branch is present it is ligated and divided.

pulmonic stenosis and overriding of the aorta. Some patients with severe disability may have little polycythemia and cyanosis.

TECHNIQUE OF OPERATION

Possible means by which the flow of blood to the lungs may be increased in the presence of the tetralogy of Fallot and similar conditions include an attack on the stenotic area itself or the use of a shunt operation in which the stenosis is by passed. The stenotic area is usually in the pulmonary conus of the right ventricle rather than in the pulmonary valve area, and excision or incision would be not only dangerous but probably would be followed by a recurrence of the stenosis at a later date. Because of this probability the better procedure would appear to be that in which some of the improperly oxygenated blood in the aorta is shunted to the lungs. This is possible because of the proximity of the thoracic aorta and its branches to the two major

branches of the pulmonary artery. It may be accomplished by anastomosing the aorta or one of the branches of the arch of the aorta to one of the two pulmonary arteries. Fortunately the pressure in the aorta and its branches is high and the pressure in the pulmonary artery and its branches is low and a good anastomosis will result in the passage of a large quantity of improperly oxygenated blood from the aorta through the lungs. An anastomosis which is properly performed between blood vessels of good caliber will almost certainly remain patent.

My associates and I have performed the following anastomoses between the systemic and pulmonary arteries in patients: (1) the proximal end of the right or left subclavian artery and the side of the right or left pulmonary artery; (2) the proximal end of the right or left subclavian artery and the distal end of the right or left pulmonary artery; (3) the proximal end of the carotid or innominate artery

Fig. 9. The relationship of the vagus and recurrent laryngeal nerves to the subclavian artery is shown. In order to obtain a long length of the subclavian artery, the ligatures are usually placed just beyond the initial branching. In the majority of cases the first branch of the subclavian is the vertebral artery. There is less danger of slipping of the ligatures if it and the subclavian are ligated separately. The subclavian artery is occluded proximally with a rubber-shod arterial clamp. The tips of the clamp are tied together in order to prevent slipping. The subclavian artery is then cut across proximal to the ligatures at its distal end.

and the side or distal end of the right or left pulmonary artery and (4) the side of the aorta and the side of one of the pulmonary arteries. The type of anastomosis which is chosen should be suited to the case in question. In general we prefer an anastomosis between the proximal end of the subclavian branch of the innominate artery and the side of one of the pulmonary arteries. The reason for this is that the subclavian branch of the innominate artery when transposed makes a much more satisfactory angle with its parent vessel than is present when the subclavian branch of the aorta is used. Since this is the method which we prefer in the majority of instances the steps of the procedure will be described and illustrated.

The side on which the aorta descends is determined preoperatively by the method of Bedford and Parkinson. If the aorta descends on the left the innominate artery is on the right; if the aorta descends on the right the innominate is on the left. Since we are desirous in most cases (with exceptions to be noted later) of using the subclavian branch of the innominate, the incision in the chest is made on the side opposite to that on which the aorta lies. This means in the majority of cases in

Fig. 10. The adventitia is removed from the end of the subclavian artery.

our experience that the incision is made on the right. With the patient lying on his back and with the side to be operated upon somewhat elevated an incision is made extending from the sternal margin to the midaxillary line. In the female the incision is made below the breast. Whereas formerly the incision into the pleural cavity was made through the third interspace it is now usually made through the second interspace except in infants when the third is chosen. The higher incision results in less interference with inflation of the lung and gives better exposure of the apex of the pleural cavity. A costal cartilage may or may not be

Fig. 11. The right pulmonary artery is occluded proximally by an especially devised rubber-shod clamp which has a long handle and which operates by a screw mechanism. Distal occlusion is produced by an ordinary rubber-shod arterial clamp. A transverse opening is made on the upper surface of the pulmonary artery. This opening should be a little larger than the end of the subclavian artery. If the pulmonary artery is quite small it may be advisable to make the opening into it in a longitudinal direction.

Fig. 9. Showing the steps of the anastomosis, reading from left to right, first above and then below. Deknatel sutures \ ooooo re used. The type of suture is an everting continuous one which includes the entire thickness of the wall of the artery. The intima is turned out and the space separating each unit is approximately one millimeter. The posterior row is placed before it is drawn taut. The ends are then tied with sutures. The anterior row is interrupted at one point. The anterior row is pulled tight as it is placed. Unlike the diagram, very little silk is visible on the interior of the blood vessels.

divided. The following 8 illustrations (Figs 6-13) picture the procedure when an anastomosis is performed between the proximal end of the subclavian branch of the innominate artery and the side of the right pulmonary artery. The position of the patient on the operating table and the location of the right pulmonary artery area and the azygos vein are shown in Figure 6. The next figure (Fig 7) represents the same region after ligation and division of the azygos vein and exposure of the right pulmonary artery. After exposure of the right pulmonary artery, dissection is carried out just beneath the superior vena cava and the innominate artery together with its branches, the right common carotid artery and the right subclavian artery is exposed (Fig 8). The right vagus and recurrent laryngeal nerves mark the position of the right subclavian ar-

tery. The right subclavian artery is occluded proximally with a rubber-shod clamp. It is ligated distally at its point of division and is cut across proximal to the ligature (Fig 9). The adventitia is then removed from the end of the subclavian artery (Fig 10). At this stage the operation is usually interrupted for several minutes and the lung is inflated. Following this rest period the right pulmonary artery is occluded proximally with a rubber-shod instrument with a long handle and is occluded distally with a bulldog clamp. A transverse opening slightly larger than the end of the systemic vessel is made between the points of occlusion on the upper surface of the pulmonary artery (Fig 11). An anastomosis is then performed between the end of the subclavian artery and the side of the pulmonary artery by the use of No. 00000 Deknatel su-

Fig. 13.

Fig. 13. Showing the completed anastomosis. The constricting devices were removed first from the pulmonary artery and subsequently from the subclavian artery. The transposed subclavian artery makes an excellent angle with its parent vessel, the innominate artery.

Fig. 14. Showing an end-to-side anastomosis between the left subclavian artery (branch of aorta) and the side of the left pulmonary artery. In contrast to the use of the subclavian branch of the innominate this method has the disadvantage that rather sharp angulation of the subclavian may occur at the point at which the subclavian arises from the aorta. On the other hand, the anastomosis is easier to perform and usually functions satisfactorily. When the lung is inflated at the completion of the procedure the angulation is lessened. Furthermore, one may elevate the position of the pulmonary artery slightly by suturing the visceral pleura of the hilus of the upper part of the lung to the mediastinal pleura. We use this method in most patients over the age of 12 because difficulty may be encountered in approximating the subclavian branch of the innominate artery to the pulmonary artery. The left pulmonary artery lies at a slightly higher level than the right.

Fig. 15. Showing an end-to-end anastomosis between the proximal end of the right subclavian artery and the distal end of the right pulmonary artery. The most frequent indications for this type are (1) a very small pulmonary artery in which an end-to-side union would be less satisfactory and (2) a short subclavian artery which it is difficult or impossible to approximate to the side of the pulmonary artery. A good end-to-end anastomosis is prefer-

Fig. 14.

Fig. 15

able to an imperfectly performed end-to-side union. In the performance of the anastomosis, three or four guide or stay sutures are placed and these are connected by continuous sutures which evert the intima.

tures. The suture is one which everts the intima of the vessels. The procedure is rendered easier if the posterior suture line is placed before it is drawn taut (Fig. 12). After it has been drawn together the two ends of the posterior row are anchored to stay sutures placed in mattress fashion. The anterior row of sutures which may be interrupted at one or more points is then placed and tied. After the anastomosis has been completed the various constricting devices are removed (Fig. 13).

It should be noted that the transposed subclavian artery makes an angle of about 90 degrees with the innominate artery and that

there is no impediment to the flow of blood. Following the establishment of the anastomosis the color of the patient usually improves strikingly and a continuous thrill can be felt in the pulmonary artery. If one uses care and patience in freeing long lengths of the pulmonary artery and the innominate and its branches one will rarely have difficulty in performing a satisfactory anastomosis between the subclavian branch of the innominate artery and the pulmonary artery in patients between the ages of 2 and 13 years.

It has been stated previously that the innominate artery arises on the left when the

Fig. 6 Showing a child in whom an anastomosis between the proximal end of the right subclavian artery and the side of the right pulmonary artery was performed 7 months after an anastomosis between the proximal end of the left subclavian and the distal end of the left pulmonary artery. It was gratifying to note that the child withstood temporary occlusion of the right pulmonary artery after the left pulmonary had been divided. This patient is doing very nicely.

aorta descends on the right and that the position can be determined preoperatively. Under such circumstances the incision is made on the left and the subclavian branch of the innominate artery is used. This operation is usually easier than a similar procedure on the right.

In the first operation which I performed for pulmonic stenosis, an anastomosis was made between the left subclavian artery which arose directly from the aorta, and the side of the left pulmonary artery. Although such an anastomosis generally functions properly the altered position of the subclavian artery usually results in rather sharp angulation at the point at which the artery arises from the aorta. The nature of the angulation is shown in a slightly exaggerated form in Figure 14. I wish to emphasize the point that such an anastomosis usually functions satisfactorily and that this procedure is usually easier technically

than a union between the right subclavian branch of the innominate and the side of the right pulmonary artery. This is because the dissection and exposure are easier and the left pulmonary artery occupies a slightly higher position than the right. In fact, we generally perform an anastomosis between the left subclavian and the left pulmonary artery in patients who are older than 12 years of age and who have attained most of their growth and in whom there may be difficulty in approximating the right subclavian to the right pulmonary artery. This is done despite the fact that it is not as ideal a procedure as the use of the right subclavian branch of the innominate. In expressing a preference for the use of the subclavian branch of the innominate over that of the subclavian which arises directly from the aorta I realize that Murray, Paine and Varco, Holman and others generally utilize the subclavian artery which arises directly from the aorta and that they are obtaining excellent results.

In the earlier phases of this work we frequently thought it necessary or advisable to use the innominate or the carotid artery for the anastomosis for the reason that the subclavian artery was regarded as too short or too small. With added experience it has been found that a short subclavian artery can generally be used if the pulmonary artery and the systemic vessel in question are dissected free of the surrounding tissues and adequately mobilized. In mobilizing the right or left pulmonary artery the dissection should be extended well beyond the initial point of branching. If one can perform the anastomosis by using the subclavian branch of the innominate, there will not be too much tension on the suture line postoperatively. Inflation of the lung after the anastomosis is completed causes it to rise somewhat in the chest and reduces tension. In other words, the limiting factor in an anastomosis is the difficulty in approximating the structures while the union is being performed and not the fear of postoperative separation of the suture line. In some of the earlier operations we frequently underestimated the size of the subclavian artery and used another vessel when the subclavian would probably have sufficed. When tension is made on the

undivided subclavian artery, it is narrowed at the point at which the subclavian artery and recurrent laryngeal nerve pass over it and appears smaller than is the actual case. There is however an occasional patient in whom we are unable to anastomose the subclavian branch of the innominate to the side of the pulmonary artery despite the employment of various maneuvers. Under such circumstances one may divide the pulmonary artery and do an anastomosis between its distal end and the subclavian artery or one may choose the innominate or the carotid artery for union to the side of the pulmonary artery. If the pulmonary artery is not more than two or three times the size of the subclavian artery I prefer the use of this vessel and the end-to-end anastomosis because of the fear of cerebral complications when using the carotid or the innominate artery. The results following a good end-to-end anastomosis (Fig. 15) are almost as satisfactory as those following an end-to-side union. If the pulmonary artery is fairly large or if for other reasons it is impossible or inadvisable to use the subclavian artery in an end-to-end or end-to-side anastomosis I think that one is warranted in using the innominate or the carotid artery despite the added risk. A long length of the carotid artery is readily available. In most instances in which the carotid has been used the subclavian had already been ligated. In two operations performed by Dr. Longmire it was determined at the outset that it would probably be impossible to use the subclavian artery and the carotid was ligated without disturbing the subclavian artery. It would seem that preservation of the subclavian and its vertebral branch would reduce the chances of cerebral complications in connection with ligation of the carotid artery.

If the right or left pulmonary artery is definitely smaller than the subclavian artery it is advisable to divide the pulmonary artery as near its point of origin from the main vessel as possible and to perform an anastomosis between its distal end and the end of the subclavian artery. If one attempts an end-to-side procedure and fails one has lost valuable length of the pulmonary artery. Further more a good end-to-end anastomosis is to be

Fig. 17 Showing the method of Potts, Smith, and Gibson of performing an anastomosis between the side of the aorta and the side of the left pulmonary artery. This ingenious clamp allows the anastomosis to be performed when the aorta is only partially occluded, thereby obviating the likelihood of paralysis of the legs. The union of intimal surfaces is not as exact as when a branch of the aorta is used and one should take care not to make the opening too large. It is my opinion that this method is particularly valuable in the treatment of infants with pulmonic stenosis in whom the subclavian artery is too small to conduct an adequate quantity of blood to the lungs. This method is difficult to use if the aorta descends on the right.

preferred to a fair end-to-side union. As was stated previously the results following an end-to-end anastomosis are usually good. I formerly thought that it would be impossible to do a second operation on the opposite side should such become necessary if the original operation had consisted of an end-to-end anastomosis. That this is not true is proved by a recent case in which an anastomosis between the end of the right subclavian and the side of the right pulmonary artery was performed 27 months after an operation on the left side in which the end of the left subclavian was anastomosed to the end of the left pulmonary artery. At the time of the first operation the child was 8 months old, the action of the heart was very poor and the left pulmonary artery was small. Some improvement followed the first operation but it was not adequate. At the second operation the patient's circulatory system withstood temporary occlusion of the

right pulmonary artery despite the fact that the left had been divided and the postoperative improvement is dramatic. A photograph of the child after the second operation is given in Figure 16.

In our initial publication on the surgical treatment of pulmonic stenosis Dr. Taussig and I (4) enumerated a number of methods by which the blood flow to the lungs could be increased. Among these was an operation in which the side of the aorta is anastomosed to the side of the left pulmonary artery. It was stated: "The third possible operative procedure is concerned with an anastomosis of the side of the aorta to the side of the left pulmonary artery. That such a procedure is possible in dogs has been shown by Leeds in his studies on patent ductus arteriosus. We considered the use of this method in our patients but were discouraged by the experience of Blalock and Park in studies on experimental coarctation of the aorta. We were fearful of causing a paralysis of the lower extremities and hence did not use this method with our patients. Another difficulty associated with the use of the aorta is that its walls are thick and rather fragile and it is difficult to obtain an accurate approximation of the intimal surfaces. I think that the last objection to the use of the aorta still holds, but the danger of paralysis has been largely removed by Potts, Smith and Gibson by the development of an ingenious clamp with which the aorta can be partially occluded while a side-to-side anastomosis to the left pulmonary artery is being performed. The employment of this clamp is illustrated in Figure 17. Although I realize that the Potts clamp may be utilized in performing anastomoses in patients of all ages, it is my opinion that its greatest field of usefulness is in infants in whom the subclavian artery is very small. It is my impression and it is only an impression that an aortic-pulmonary artery anastomosis places a greater strain upon the heart than a communication of the same size between a branch of the aorta and the pulmonary artery. There are many cases in which the pulmonary artery is too small for a satisfactory anastomosis with the side of the thick-walled aorta."

use of the aorta is usually accompanied sacrifice of a large number of collateral

arterial pathways to the lungs than is the case when one of the aortic branches is employed. Even though one prefers to utilize the subclavian artery everyone who is doing this type of surgery should have the Potts clamp available. For example if one makes an incision on the left in an adult with the idea of using the subclavian branch of the aorta, one may decide to do an aortic anastomosis if for some reason the subclavian artery is unsatisfactory.

The principle underlying all of the operative procedures which have been mentioned is the same, namely by passing the point of stenosis in the pulmonary artery and allowing poorly oxygenated blood in the aorta to pass through the lungs. The surgeon performing this type of work should be thoroughly familiar with the anatomy of the region, should be able to do end-to-side, end-to-end, and side-to-side anastomoses and should be able to use the subclavian artery, the carotid artery, the innominate artery or the aorta according to indications. The same procedure does not fit all cases. As I stated previously the subclavian artery may be too small or too short. The aorta is not suitable if the pulmonary artery is very small in size. Obviously under such conditions one could perform a better anastomosis by using a smaller, thinner-walled vessel such as the subclavian artery.

There is always a systemic vessel which can be used for the anastomosis. The limiting factor is the pulmonary artery. If there is no pulmonary artery or if the artery is diminutive in size, one is obviously defeated. The size of the aorta and its branches varies greatly. Some small children have large systemic arteries when this is the case the pulmonary artery is apt to be small.

A later section of this paper will deal with anomalies of the blood vessels. At this point it should be emphasized again that one should know preoperatively the position of the aorta for this is of importance in determining the side on which the operation is performed. If the aorta descends on the right and one wishes to use the subclavian branch of the innominate, the incision is made on the left. If the aorta descends on the right and one wishes to use the aorta, obviously the incision is made on the right.

There are several reasons for our preference not to operate upon infants under the age of 2 and for the present policy of not advising operation in infants if it is thought that there is a 50 per cent chance that the infant will survive to be 2 years of age or older. Among the reasons are the facts that it is more difficult to be certain of the diagnosis in infants that the operative mortality is higher and that the anastomosis has by necessity to be a rather small one. Even though the aorta is used, one does not dare to make a large communication between the two vessels in infants because of the danger of causing heart failure. It is not known whether the anastomosis increases in size with the growth of the vessels. It seems likely that some of the patients operated upon in infancy will have to have a second operation at a later date.

The present ideas in regard to the type of operation as related to the age and size of the patient are roughly as follows

A. Patients under 2 years of age.

- 1 Do not operate if the chances of survival to 2 years of age are 50 per cent or better
- 2 Make the incision on the side on which the aorta descends. Use the subclavian artery if it appears large enough. If not, perform side-to-side anastomosis between the aorta and the pulmonary artery

B. Patients 2 years to 12 years of age.

- 1 Make the incision on the side opposite to that on which the aorta descends. The preferred anastomosis is between the subclavian branch of the innominate and the side of the pulmonary artery
- 2 If the pulmonary artery is very small, do an end-to-end anastomosis between the subclavian artery and the distal end of the pulmonary artery

C. Patients more than 12 years of age or more than 5 feet in height or both 12 years of age and 5 feet in height.

- 1 If the aorta descends on the left, make the incision on the left. Perform by preference an anastomosis between the subclavian branch of the aorta and the side of the left pulmonary artery. If this is impossible and if there is not too great discrepancy in the sizes of the subclavian and pulmonary arteries perform an end-to-end anastomosis. An alternative method is an anastomosis between the side of the aorta and the side of the left pulmonary artery
- 2 If the aorta descends on the right, make the incision on the left and use the subclavian branch of the innominate artery for the anas-

Fig 18 Showing a right aortic arch with an aorta which descends on the right. The position of the descending aorta is of importance from a surgical standpoint in that it determines the side on which one makes the incision. The innominate arises on the side opposite to that on which the aorta descends. In most of the cases in which the aorta descends on the right there is an obliterated ductus arteriosus which connects the pulmonary artery with the first portion of the left subclavian artery

tomosis. This blood vessel is usually a long one and furthermore the left pulmonary artery is usually at a higher level in the chest than the right pulmonary artery

ANOMALIES OF THE BLOOD VESSELS

This description of blood vessel anomalies is by no means all inclusive. It is simply a brief account of some of the anomalies most of which have been observed in the course of operations on our patients.

Right aortic arch If the aorta arches to the right and descends upon the right, the condition is termed a right aortic arch. The three major vessels which arise from the arch of the aorta are the mirror image of normal that is the innominate artery arises first and passes toward the left the right common carotid arises next and the right subclavian artery last. The condition places no undue strain on the heart and is usually of importance only in that it may influence the side upon which the operation for pulmonic stenosis or atresia is performed. By and large the easiest anastomoses which we have performed are in patients with a right aortic arch because the left subclavian branch of the innominate is usually a

Fig. 9 Showing double aortic arch or aortic ring. The patient died suddenly on the fourteenth postoperative day after the creation of an artificial ductus for pulmonic stenosis.

long vessel and can be approximated to the left pulmonary artery without difficulty. As stated previously the presence of a right aortic arch can be determined by the method of Bedford and Parkinson. Dr. Taussig and her associates have been in error as to the position of the aorta in only 2 or 3 of our cases.

A right aortic arch occurs so often that perhaps it should not be regarded as an anomaly. It has been found in 144 of the 610 cyanotic patients upon whom we have operated. It has been surprising that the incidence is so high in view of the fact that the late Dr. Maude Abbott found only 35 cases in 20 analyses of autopsies on 1,000 cases of congenital heart disease. In 14 of these the right aortic arch was the "primary" lesion whereas in 21 cases it was associated with other defects.

In approximately three-fourths of the patients with a right aortic arch upon whom we have operated there has been an obliterated ductus arteriosus connecting the first part of the left subclavian branch of the innominate to the pulmonary artery. This is a long fibrous structure which in some instances has a small lumen at either the systemic or the pulmonic end. This has been a surprising observation in view of the belief that in a right aortic arch the sixth right branchial arch distal to the pulmonary artery persists as the ductus arteriosus. The usual finding in our cases is shown in Figure 18. In our experience with the right aortic arch the ductus has not always been on the left and furthermore Dr. John Jones has operated upon a patent ductus on the right in a patient with a right aortic arch.

Fig. 20. Autopsy specimen showing a pulmonary artery to only one of the lungs. Such a condition should be suspected as a result of preoperative studies and the observations at the time of operation.

In some instances the aorta arches to the right but then turns sharply to the left and descends on the left. This is known as a right aortic arch with a left descending aorta. Under such conditions the aorta lies behind the esophagus and is called a retro-esophageal aorta. The point of origin of the arteries from the arch is variable. In some cases the left subclavian artery arises from the descending aorta.

A patient was operated upon recently who had the rare combination of a left aortic arch, a retro-esophageal aorta, and a right descending aorta. This case is being reported by Dr R. N. Paul.

In a patient with dextrocardia the aorta may descend on the right or the left. This statement is true whether there is or is not a complete situs inversus. Dr Taussig has found that a left aortic arch occurs in a high percentage of patients with dextrocardia. From the surgical standpoint the important fact to remember is that the innominate artery arises on the right when the aorta descends on

the left and on the left when the aorta descends on the right. Furthermore the prognosis should be very guarded in patients with dextrocardia particularly if there is not situs inversus. Additional malformations of the heart and blood vessels are likely to be present.

It should be emphasized that these observations on the aortic arch are largely of academic interest except as the position influences the site from which the large vessels arise and hence the side on which the incision is made. It is true that patients with abnormal position of the great vessels may have dysphagia lusoria but this was not encountered in this series of patients.

Double aortic arch. A double aortic arch or aortic ring is a rare malformation. The aorta arches to the right and descends on the left. It occurs as a result of the persistence of both the right and the left fourth aortic arches as functioning tubes. Thus the double aorta encircles the trachea and the esophagus. The origin of the great vessels from the double arch is variable.

Fig. 19. Showing the right subclavian in a position posterior to the trachea and esophagus. The position can be determined by inspection and palpation. Furthermore, the fact that the vagus nerve does not pass across the subclavian artery leads one to suspect an abnormal position.

Fig. 20. Showing the transposed position of the retro-esophageal subclavian artery. In most instances in which this anomaly is encountered the subclavian artery has not been brought out anterior to the trachea and esophagus.

I am aware of only one patient with a double aortic arch in association with the tetralogy of Fallot upon whom I have operated, and the double aortic arch was not recognized at the time of operation. An anastomosis between the end of the right subclavian artery and the side of the right pulmonary artery was performed on this 20 year old girl from France. She did well in the early postoperative period but died suddenly of what was thought to be a cerebral embolus on the fourteenth postoperative day. At autopsy a large thrombus in the left ventricle was seen. The double

aortic arch is shown in Figure 19. It is very likely that an aortic ring was present in a few of the other patients in whom an artificial ductus was created.

Single pulmonary artery Observations at the time of operation or autopsy in 9 of the patients indicate that there was a pulmonary artery to only one of the two lungs. Such a finding should be suspected in preoperative studies in which the vascular markings on the one side are less pronounced than those on the opposite side. Furthermore the condition should be suspected at the time of operation

Fig. 21. Showing retro-esophageal innominate artery on the left.

Fig. 22. Anastomosis between subclavian branch of a retro-esophageal innominate and left pulmonary artery.

Fig 25. The condition in a patient who had a right aortic arch and in whom the incision was made on the left is shown. In approximately the position in which the innominate artery should have been located there was an obliterated cord which connected the junction of the left subclavian and left carotid arteries with the pulmonary artery. Palpable arterial pulsations were present in the subclavian and carotid arteries.

if the action of the heart becomes impaired during temporary occlusion of the right or left pulmonary artery or if the pressure in the pulmonary artery rises noticeably during the occlusion period. If the collateral circulation to the lungs is well developed a patient with a single pulmonary artery may withstand occlusion of this vessel for a sufficiently long time to allow for the performance of an anastomosis. It is doubtful however if the risk is warranted if the presence of a single pulmonary artery is strongly suspected. The condition seen at autopsy in a patient who had a single pulmonary artery is shown in Figure 20.

Retro-esophageal subclavian artery This anomaly has been observed in 26 patients. In 12 of these the operation was being performed on the right side. In none of these was there a history of difficulty in swallowing. In a number of the patients an abnormality in position of the subclavian artery was suspected preoperatively because of a slight de-

formity of the esophagus as observed on the x ray film after the swallowing of barium. In most of the cases in which a retro-esophageal subclavian artery was found the anastomosis

Fig 26 Showing an anastomosis between the junction of the left subclavian and carotid arteries (Fig 25) and the left pulmonary artery. The patient improved strikingly after operation.

Fig. 27. Showing a large unidentified vessel on the right. It was thought to be ductus arteriosus. It arose from the innominate and was almost as large as the innominate. It became progressively smaller as it approached the pulmonary artery area. The flow of blood was from the innominate end. Patency of the opposite end was not demonstrated.

between it and the pulmonary artery was performed without altering essentially the position of the subclavian. In several instances the right subclavian artery was delivered to the left of the right bronchus and the esophagus after it had been divided distally and the anastomosis was performed anterior to these structures. Diagrams of the preoperative and postoperative positions in one of these patients are shown in Figures 21 and 22. In any case the retro-esophageal location of a subclavian artery is not a deterrent to the performance of a satisfactory anastomosis. The wall of a retro-esophageal subclavian artery is thinner than that of the same vessel in a normal position.

Retro-esophageal innominate artery. A retro-esophageal innominate artery has been ob-

served in only one of our patients. The abnormal position of this blood vessel presented no unusual difficulties in the creation of an artificial ductus arteriosus. The condition at the time of operation before and after the performance of the anastomosis is shown in Figures 23 and 24.

Absence of innominate artery. The four great vessels, the two subclavian arteries and the two common carotid arteries may arise directly from the aorta in which case the innominate artery is absent. The opposite extreme is found in cases in which both common carotid arteries as well as one of the subclavian arteries arise from the innominate. The identity of the great vessels must be determined with care at the time of operation and the surgeon should ask the anesthetist to ascertain

Fig. 28 Anastomosis between the unidentified vessel shown in the previous figure (probably a ductus arteriosus) and the right pulmonary artery

Fig. 29 Showing a functional truncus arteriosus with a blind right pulmonary artery. Subsequent autopsy did not disclose a pulmonary artery on the left. The circulation to the lungs was entirely through collateral arterial channels.

the effect on the peripheral pulse of temporary occlusion of the blood vessel under consideration for ligation. In this way the unnecessary use of one of the carotid arteries may be avoided.

An unusual anomaly in which the presence of an innominate artery was not demonstrated is shown in Figure 25. A band of fibrous tissue without a lumen connected the junction of the left common carotid artery and the left subclavian artery with the pulmonary artery. This patient had a right aortic arch; hence the innominate artery should have been on the left. Pulsations were palpable in the carotid and subclavian arteries but the origin of the vessels was not determined. The performance

of an anastomosis between the junction of these arteries and the left pulmonary artery resulted in definite improvement in the patient (Fig. 26).

Unusual ductus arteriosus It was the consensus among us that the large blood vessel shown in Figure 27 was a ductus arteriosus which was obviously patent at the innominate end and which may or may not have been patent at the opposite end. The innominate

Fig. 30 Showing an anastomosis between the right subclavian artery and the patent distal end of the pulmonary artery shown in the previous figure. The patient, who died as the anastomosis was being completed, should have been greatly improved if the operation had been tolerated.

Fig. 31 Showing the presence of bilateral superior venae cavae, a frequent anomaly. The entrance of the left superior vena cava into the heart is variable.

Fig. 32. This interesting anomaly shows the superior and inferior venae cavae on the left and the left superior pulmonary vein entered approximately at the junction of these vessels.

end of this vessel was only slightly smaller than the innominate artery itself and it became progressively smaller as it approached the region of the base of the heart. The pulsating stream of blood originated from the

innominate end of the vessel. Even though we could not be certain as to the point of attachment or the lack of patency of the opposite end of the vessel it was cut across and an anastomosis to the right pulmonary artery was performed (Fig. 28). The patient showed striking improvement following the operation.

Functional truncus arteriosus with blind pulmonary artery. Several patients have been operated upon in whom the pulmonary artery did not connect with the heart or the aorta. The circulation to the lungs was by way of collateral vessels usually bronchial arteries. An example of this condition is illustrated in Figure 29. An end-to-end anastomosis was performed between the right pulmonary artery and the right subclavian artery but unfortunately the heart's action ceased suddenly just as the union was completed (Fig. 30). Autopsy examination showed that there was no communication on either side between the pulmonary artery and the heart or aorta and

Fig. 33. Showing an anastomosis between the left innominate artery and the left pulmonary artery in the presence of the anomaly shown in the previous figure. Under such conditions the transposed artery should not be placed in such position that it will press upon the vein.

Fig. 34. Showing an anomalous position of the superior vena cava. The superior pulmonary vein entered the superior vena cava.

that the circulation to the lungs was through collateral vessels. The patient should have been greatly improved if the operative procedure had been tolerated.

Bilateral superior venae cavae. The presence of bilateral superior venae cavae is not a rare anomaly. With the increased use of venography a surprisingly large number of cases have been discovered. Since exploratory thoracotomy exposes the contents of only one pleural cavity, it is difficult to make the diagnosis by operation alone. It is true, however, that a left superior vena cava has been observed in a number of the patients in whom the incision was made on the left. When bilateral superior venae cavae are present, both veins may open into the right auricle or one may enter the right and the other the left auricle or one may enter the right auricle and the other the coronary sinus. An illustration depicting the entrance of the right superior cava into the right auricle and the left into the coronary sinus is shown in Figure 31.

Other anomalies of systemic veins. Other anomalies range from those in which both the

superior and the inferior venae cavae enter the left auricle to minor variations in position of the various vessels. The presence of both the superior and the inferior venae cavae on the left as observed at the time of operation is shown in Figure 32. The site of entrance into the heart was not determined. It was noted that the left superior pulmonary vein entered these vessels. The type of arterial anastomosis which was performed is shown in Figure 33. It is important to place the systemic artery which is used for the shunt in such position that it will not press on the superior or inferior vena cava.

A peculiar position of the superior vena cava as observed in an operation on the right side is shown in Figure 34. The superior pulmonary vein emptied into this vessel. The anastomosis between the subclavian artery and the pulmonary artery is shown in Figure 35.

An anastomosis on the right side was made more difficult in a case in which the left innominate vein passed posterior to the innominate artery and almost circumscribed it (Fig

Fig. 35. Showing the anastomosis between the right subclavian artery and the right pulmonary artery in the presence of the anomalous position of the superior vena cava as depicted in Figure 34.

36) The completed anastomosis is depicted in Figure 37

Anomalies of pulmonary veins Some or all of the pulmonary veins may drain into the right auricle or its tributaries. Two such cases are shown in drawings in the preceding section. Despite the fact that no attempt was made to alter the site of the drainage in these cases at the time that an artificial ductus arteriosus was created the patients have improved greatly.

Brody, Brantigan and others have reported similar anomalies of the pulmonary veins and have reviewed the literature. With further improvement in diagnostic methods and surgical technique some of these anomalies can probably be treated successfully by operation.

TREATMENT AND RESULTS

The preoperative and postoperative care of most of the patients is not very difficult or complicated. Digitalis is recommended before operation for patients in whom the cardiac rate is low. The removal of the

section is seldom if ever indicated. Care should be exercised in the preoperative period to see that the patient does not become dehydrated because of the possibility that cerebral thrombosis may occur. A child should receive at least 1600 cubic centimeters of fluid per diem and an adult at least 2500 cubic centimeters per diem. The administration of penicillin should be begun before or shortly after the operative procedure.

The total quantity of fluids administered during the operation should equal approximately the loss of blood during the procedure. Unless blood loss is excessive the fluid is given in the form of plasma. If severe bleeding occurs, whole blood is administered. If the pulse rate should become alarmingly slow additional atropine is given.

All patients are placed in an oxygen tent on being returned to their rooms. Venesection is rarely performed. Aspiration of the pleural cavity on one or more occasions is performed in at least half of the cases. The administration of blood is indicated if a large accumula-

Fig. 36 Showing an anomalous position of the left innominate vein in which it lies posterior to the innominate artery

tion of blood in the pleural cavity occurs. The problem as to the quantity of fluid other than blood which should be given is a delicate one. The quantity should be sufficient to reduce the likelihood of cerebral and anastomotic thrombosis and should not be sufficient to cause pulmonary edema and heart failure. In general the total fluid intake each 24 hours in the early postoperative period should be 700 to 900 cubic centimeters in infants, 1,000 to 1,400 cubic centimeters in children and 1,800 to 2,200 cubic centimeters in adults. If evidence of cerebral thrombosis or occlusion of the anastomosis appears the administration of heparin is indicated. It is important to bear in mind that these patients need rest in the postoperative period and that they may be overtreated as well as undertreated.

My associates and I have operated upon 610 cyanotic patients who were believed as a result of preoperative studies by Dr. Taussig, Dr. Bing, and others to have an inadequate flow of blood to the lungs. With the exception of 15 patients who were operated upon in Guy's Hospital in London and Hôpital Broussais in Paris, the operations were performed in

the Johns Hopkins Hospital. A second anastomosis has been carried out on several of the patients. The total number of patients who have died is 108, an overall mortality rate of 17.7 per cent. Twenty-seven of the deaths occurred during the operation, 68 in the postoperative period, and 13 after discharge from

TREATMENT AND RESULTS

The preoperative and postoperative care of most of the patients is not very difficult or complicated. Digitalis is recommended before operation for patients in whom the cardiac reserve is low. The removal of blood by vene-

section is seldom if ever indicated. Care should be exercised in the preoperative period to see that the patient does not become dehydrated because of the possibility that cerebral thrombosis may occur. A child should receive at least 1 600 cubic centimeters of fluid per diem and an adult at least 2 200 cubic centimeters per diem. The administration of penicillin should be begun before or shortly after the operative procedure.

The total quantity of fluids administered during the operation should equal approximately the loss of blood during the procedure. Unless blood loss is excessive the fluid is given in the form of plasma. If severe bleeding occurs, whole blood is administered. If the pulse rate should become alarmingly slow additional atropine is given.

All patients are placed in an oxygen tent on being returned to their rooms. Venesection is rarely performed. Aspiration of the pleural cavity on one or more occasions is performed in at least half of the cases. The administration of whole blood is indicated if a large accumula-

Fig. 36. Showing an anomalous position of the left innominate vein in which it lies posterior to the innominate artery

tion of blood in the pleural cavity occurs. The problem as to the quantity of fluid other than blood which should be given is a delicate one. The quantity should be sufficient to reduce the likelihood of cerebral and anastomotic thrombosis and should not be sufficient to cause pulmonary edema and heart failure. In general the total fluid intake each 24 hours in the early postoperative period should be 700 to 900 cubic centimeters in infants, 1,000 to 1,400 cubic centimeters in children and 1,800 to 2,200 cubic centimeters in adults. If evidence of cerebral thrombosis or occlusion of the anastomosis appears the administration of heparin is indicated. It is important to bear in mind that these patients need rest in the postoperative period and that they may be 'over treated as well as undertreated.

My associates and I have operated upon 610 cyanotic patients who were believed as a result of preoperative studies by Dr. Taussig, Dr. Bing and others to have an inadequate flow of blood to the lungs. With the exception of 15 patients who were operated upon in Guy's Hospital in London and Hôpital Broussais in Paris, the operations were performed in

the Johns Hopkins Hospital. A second anastomosis has been carried out on several of the patients. The total number of patients who have died is 108, an overall mortality rate of 17.7 per cent. Twenty-seven of the deaths occurred during the operation, 68 in the postoperative period and 13 after discharge from

Fig. 37. Showing the relationship between the subclavian pulmonary arterial anastomosis and the innominate vein as demonstrated in Figure 36

the hospital. No known deaths are excluded. Some of the patients did not have a pulmonary artery which was suitable for anastomosis and death followed simple exploratory thoracotomy. The diagnosis was in error in some fatal cases. 7 of these patients had a transposition of the aorta and pulmonary artery. A few of the deaths were unrelated to the operative procedure, for example a child from France died of meningitis after returning home.

Twelve of the 27 deaths which occurred during operations were in the course of exploratory thoracotomies. In some of these instances the pulmonary artery was absent or was not suitable for an anastomosis. Six of the patients died while an anastomosis was being performed and 9 succumbed shortly after the blood vessel union was completed. In some instances the exact cause of death was not determined but it seems reasonably certain that the commonest cause of death during the operative procedure was cardiac anoxia.

Sixty-eight of the patients succumbed during the postoperative hospital period. In many instances the cause was not determined. The major cause or the contributing cause was thought to be cerebral thrombosis in 24 cases, cardiac failure or pulmonary edema in 16 cases, hemorrhage in 8 cases, thrombosis of the anastomosis in 5 cases and respiratory complications in 3 cases. As was stated previously, autopsy examination did not explain the fatal outcome in a number of cases.

There have been 13 patients who died after discharge from the hospital from varied causes, some of which were not related to the operation. Included among the causes of death were heart failure, coronary occlusion, pneumonia, and cerebral accidents.

The mortality rate depends to a considerable extent upon the principles which one adopts in regard to operability. We have taken the position that almost all cyanotic patients who are believed to have an inadequate pulmonary blood flow and who are significantly incapacitated should be operated upon. The mortality rate in patients 2 years of age and older with a typical tetralogy of Fallot is low. We have had as many as 44

consecutive operations without a death. On the other hand the danger is considerably greater when patients have associated complications such as rotation of the heart and cardiac arrhythmias. The ideal set of conditions on preoperative study and at the time of operation are a moderate reduction in pulmonary blood flow, a normal sized or only slightly enlarged heart, a large and long subclavian artery, a pulmonary artery of moderate size, few collateral arterial channels to the lungs, a high pressure in the aorta and its branches and a low pressure in the pulmonary artery and a patient in the age group of 3 years to 10 years. On the other hand, a more unfavorable prognosis accompanies operations on patients with heart failure, arrhythmias, rotation of the heart, a greatly enlarged heart (cardio-thoracic ratio 60+) or absence of a systolic murmur in the pulmonary area (suggestive of atresia). The outlook is particularly poor in infants.

An anastomosis between the proximal end of one of the subclavian arteries and the side of one of the pulmonary arteries has been performed in 433 patients who survived the termination of the operative procedure itself. In most of these the subclavian branch of the innominate was used. There were 45 deaths in the 433 cases, a mortality rate of 10.4 per cent. The diagnosis was in error in a few of the fatal cases. An anastomosis between the proximal end of a subclavian artery and the distal end of one of the pulmonary arteries was performed in 38 cases with 6 deaths, a mortality rate of 15.7 per cent. In most patients in this category the pulmonary artery was considered to be too small for a satisfactory end-to-side anastomosis.

Most of the cases in which the innominate or the carotid artery was used for the anastomosis were in the earlier part of the series. It is our opinion at present that it is rarely necessary to use one of these larger blood vessels, in the great majority of cases adequate mobilization of the arteries will allow one to use the subclavian artery. At any rate the carotid artery has been employed for the anastomosis in 34 cases with 8 deaths, a mortality rate of 23.5 per cent, and the innominate in 49 cases with 15 deaths, a mortality rate of

30.6 per cent. There is no doubt that ligation of the innominate or the carotid artery exposes the patient to a greater risk of cerebral complications. It is only fair to state however, that a number of the patients in this group were small, very sick children, and that part of the high mortality is ascribable to the poor general condition of the patients. A side-to-side anastomosis between the aorta and the pulmonary artery has been performed in only 2 cases with 1 death. In this fatal case the anastomosis was made too large and pulmonary edema developed. There were 24 exploratory thoracotomies with 4 deaths; no anastomosis being performed for various reasons.

The right or left subclavian artery has been ligated in approximately 555 cases. In most instances the ligatures were placed just distal to the point at which the vertebral artery arose the subclavian and the vertebral being ligated separately. There has been no serious interference with the circulation of the arm in any of these patients. Sympathetic nerve block has not been used. The affected extremity is slightly cooler than the opposite one for a while and a radial pulse is absent for an extended period. There has been no discernible impairment in function of the arm and hand in any instance.

The majority of the patients who have survived the operative procedure are improved. The degree of improvement ranges from that observed in some patients who seem to have no further limitations in activity to those who have definite restrictions. The detailed results in the first 300 cases will be reported shortly by Dr. Ruth Whittemore. Most of the patients show improvement in the color of the mucous membranes as soon as the anastomosis is established and blood studies demonstrate an elevation in the arterial oxygen saturation. During the following days and weeks the ar-

terial oxygen saturation continues to rise somewhat and the oxygen capacity, the hemoglobin, the red blood cell count, and the packed cell volume decline. The clubbing of the fingers and toes usually recedes gradually. The pulse pressure generally becomes greater than that found in the preoperative period and a continuous murmur is heard in the precordial area. The most notable alteration, however, is the lessening of the patient's incapacity. Many of the patients in the postoperative period appear to be amazingly free of limitations. Some of the patients who could walk only a few steps before operation can now walk miles. It must be emphasized, however, that the time since operation has been too short to allow an evaluation of the final results.

SUMMARY

In this lecture in honor of Doctor Rudolph Matas the surgical procedures employed and the anatomical variations encountered in the treatment of 610 cyanotic patients with a preoperative diagnosis of pulmonic stenosis have been enumerated, considered and illustrated. A brief account of the postoperative results has been given.

BACTERIOLOGY OF THE VAGINA IN 75 NORMAL YOUNG ADULTS

FRANK R. LOCK, M.D., MARTHA DUKES YOW M.D., MARY L. GRIFFITH, M.D. and
CAROLYN STOUT A.B., Winston-Salem, North Carolina

SINCE the development of newer bacteriological methods few studies have been made of the organisms in the vagina of normal human adults. Topley and Wilson (21) discuss briefly the normal flora of the vagina after puberty naming Doederlein's bacillus as the predominant organism and mentioning several other frequent inhabitants including staphylococci streptococci coliform bacilli and diphtheroids.

In 1944 Rakoff analyzed the biologic characteristics of the vagina in 500 normal adults, 37 of whom were followed three times weekly through 1 to 3 menstrual cycles. In these he correlated vaginal acidity with the conventional grades of vaginal flora grade I Doederlein's bacilli only grade II Doederlein's bacilli and other organisms, grade III, organisms other than Doederlein's bacilli. He concluded that the normal vaginal flora is associated with pH 3.9 to pH 6.1 and consists of lactobacilli only. However he conceded that apparently normal vaginas may harbor other organisms, such as staphylococci, streptococci diphtheroids, coliform organisms, and yeast like forms.

The recent report of Hite, Hesselstine and Goldstein (10) concerning 248 normal and pathologic patients does not classify the subjects as pregnant and nonpregnant. It therefore is not suitable for analysis of the flora in normal nonpregnant adults.

In 1936 Weinstein and his associates (25) made a survey of the vaginal flora at various ages in a group of 99 nongravid adults with marital introitus and with normal menstrual histories. Forty five of these had leucorrhea and cervicitis, while 54 had normal vaginal tracts. In this group of 99 by examining smears, he divided the flora into three groups

which differed from the conventional grades in that Doederlein's bacillus was included in group III as well as in groups I and II, and group III was distinguished from group II by the presence of diphtheroids. A similar classification could not be made from cultures. He listed the pelvic lesions associated with various bacteria but did not give the complete flora of any of the normal individuals.

In 1938 Weinstein (23) reported a study of 375 patients, including healthy unhealthy pregnant and nonpregnant individuals. He could find no correlation between vaginal pH and the type of flora nor could he group the flora into conventional grades.

Some of the organisms frequently cultured from the vagina have been studied in detail. Soule and Brown (17) reviewed the literature concerning anaerobic streptococci in the vagina, quoting positive cultures in 40 per cent of apparently normal women (Rosowski). The other studies reviewed as well as the series of Soule and Brown dealt with pregnant individuals.

Hite and Hesselstine (11) recently isolated 92 strains of streptococci from the vagina and uterus. This procedure however as well as their review of the literature deals chiefly with pregnant and postpartum patients.

Likewise studies of staphylococci from the human vagina frequently are based on cultures from prenatal and postpartum patients. Weinstein's series (24) included 233 cases of nonpregnant women, with an incidence of 48.8 per cent cultures positive for staphylococci. From his total series of 419 individuals, he isolated 19 strains of staphylococci, many of which gave reactions suggestive of pathogenicity.

Surprisingly the Doederlein bacillus, though considered the predominating vaginal organism, is of uncertain identity. Bergey's *Manual of Determinative Bacteriology* describes 15 defi-

From the Department of Obstetrics and Gynecology of the Bowman Gray School of Medicine at Wake Forest College, Winston-Salem, N. C.

nite and 8 possible species of lactobacilli but does not mention the vagina as a source for any of them. The description of *Lactobacillus acidophilus* corresponds fairly well with the characteristics usually ascribed to the Doederlein bacillus. Although Topley and Wilson use the term Doederlein's bacillus in discussing the vaginal flora, they state elsewhere (20) in the same text in discussing lactobacilli. It seems probable that some species that have been called by different names are in reality identical. It seems likely that Doederlein's bacillus for example, is the same as *Lactobacillus acidophilus*. The text of Jordan and Burrows recalls the old synonyms of Doederlein's bacillus: *Bacillus vaginalis* and *Bacillus crassus* and states that it is a common constituent of the flora of the vagina. However they dismiss a detailed discussion of it with the statement that it is thought to be identical with *Lactobacillus acidophilus*. The term Doederlein's bacillus and its synonyms seem to be disappearing quietly from the newer editions of text books of bacteriology.

Independent investigators have conflicting views as to the identity of the vaginal lactobacillus. Thomas reviewed the conflicting ideas in the literature from the time of Doederlein's original description in 1891 until 1926. His own work in 1928 consisted of a study of the microscopic, cultural and serological characteristics of organisms from 107 specimens obtained from normal vaginas, including 8 strains of lactobacilli. His final conclusion based chiefly on agglutination reactions was that Doederlein's bacillus is *Lactobacillus acidophilus* and that "no new names for the vaginal bacilli are justified. Lash and Kaplan however believed that of their four strains of Doederlein's bacilli, two were identical with strains of *Lactobacillus acidophilus* one with *Corynebacterium segmentum* but that one, strain B, deserved the name *Lactobacillus vaginae*. Likewise Brown and Redwitz reported serological differences between Doederlein's bacillus and *Lactobacillus acidophilus*.

Previous investigators of the vaginal flora have tended to concentrate their attention on the cultural characteristics of certain bacteria

or to enumerate the complete range of organisms isolated without a clear division of their source from normal or abnormal subjects. A search of the literature fails to reveal a complete list of vaginal organisms obtained from a group of healthy women. Thus the interpretation of vaginal cultures is confused by ignorance in regard to the range of physiological variations of the vaginal flora. The present investigation was prompted by the need to establish such a distinction in various age groups. The preliminary study to be reported is concerned with the vaginal organisms from a group of seemingly healthy young women.

METHODS

Material. Student nurses without signs or symptoms of gynecologic disease were used as volunteers. Ages ranged from 17 to 25 years. None were married. In several instances the material was discarded because of technical difficulties such as contamination when the introitus was very small. The series to be reported consists of 75 cultures and smears.

Technique of obtaining material. The device used for obtaining cultures consisted of a cotton swab on a wooden applicator about 12 centimeters in length, contained in No. 7 glass tubing about 8 centimeters long. The bore was just large enough to allow free movement of the swab. The devices were kept in separate cotton plugged glass test tubes of suitable length.

No perineal clean up was used. The labia were parted widely in such a manner that pressure was directed toward the perineum, and the hymenal opening was made to gape. Through this opening the glass cylinder was passed well into the vagina without touching the introitus or lower vaginal walls. The swab was then pushed from its protected position inside the glass container and was carried 2 to 4 centimeters higher in the vagina. After the swab had been twirled a few times it was withdrawn into the tube, and the tube withdrawn from the vagina. With the labia still separated one end of a strip of nitrazine paper was then passed into the lower vagina and allowed to become moist. By comparing this with color charts, the pH was determined. This procedure was not carried out in 7 of the 75

TABLE I—VAGINAL ORGANISMS CULTURED FROM 75 UNMARRIED HEALTHY YOUNG WOMEN*

Saccharomyces		1.3
Cryptococcus species	1	1.3

*Specimens from subjects showed no growth

After cultures were planted the swabs were used to make a smear for Gram's stain and to make a saline suspension which was used in searching for trichomonads.

Culture methods. All cultures were planted immediately usually within 5 minutes after obtaining the material. Cultures were set up as follows: (1) aerobic blood agar plates, pH 7.3 incubated at 37 degrees for 24 hours; (2) anaerobic blood agar slant, pH 7.3 incubated at 37 degrees for 4 to 48 hours; (3) chocolate blood agar plates, pH 7.3 under about 10 to 20 per cent CO₂ tension for 48 hours; (4) Sabouraud's slant at room temperature for 1 to 2 weeks.

In some instances, the aerobic and anaerobic cultures were first incubated 18 to 24 hours in B. B. L. Brewer's thioglycollate broth and then subcultured to the blood agar plates and slants. Blood agar plates were made by adding human blood to bacto-nutrient agar. Chocolate agar plates were made by adding fresh sterile defibrinated blood to hot bacto-proteose No. 3 agar. Anaerobiosis was achieved by placing the agar slant in a larger tube containing sodium hydroxide pellets and pyrogallol acid crystals and about 1 cubic centimeter of water. The large tube was then closed with a cork stopper and sealed with melted paraffin. The chocolate agar plates were incubated in a candle-jar to provide carbon dioxide. Colonies which grossly and on stained smear seemed to belong to the coliform group of organisms were subcultured to desoxycholate plates and to

TABLE II—GROWTH OF STREPTOCOCCI FROM VAGINA UNDER VARIOUS ATMOSPHERIC CONDITIONS

carbohydrate fermentation tubes. On anaerobic plates colonies of lactobacilli and diphtheroids were usually identified by their gross appearance and by their appearance in stained smears. Pigment formation of staphylococci was determined by subculture to milk agar. Sarcinae were identified by yellow pigment and by the typical cubical arrangement. The *C. albicans tetragenia* was identified by the typical arrangement in tetrads. Both aerobic and anaerobic streptococci were transferred to thioglycollate broth to check for chain formation from the broth and blood agar poured plates were made to determine the type of hemolysis. In the single growth of beta streptococci the Lancefield grouping was not determined. When the chocolate agar plates had colonies suggestive of *Neisseria* they were subjected to the oxidase test by flooding with a solution of 10 milligrams of p-aminodimethylaniline monohydrochloride in 1 cubic centimeter of water. False positive reactions were frequently encountered especially with gram positive rods but were not confusing since the color faded within a few minutes.

The lactobacilli on chocolate agar were easily identified as dry colonies usually imparting a green discoloration to the medium. Microscopically they had a typical long-chained arrangement and took the Gram's stain irregularly.

Yeast-like organisms were identified and the species of *Candida* differentiated by the commonly accepted methods (7-18) of identifying hyphae, mycelia buds and chlamydospores. Subcultures were made to cornmeal-dextrose agar plates and fresh carbohydrate fermentation tubes which were then overlaid with vaseline. For final identification of *Cand-*

Total	75	99.99

S. albidus a 2 per cent suspension in saline was injected into the marginal ear vein of a rabbit

RESULTS

1 Organisms demonstrated, their incidence and cultural characteristics The organisms cultured and their incidence are shown in Table I. Of the 24 growths of streptococci, 14 were nonhemolytic, 7 alpha 1 beta, and 2 unidentified. The streptococci were interesting in their frequent failure to grow aerobically. In the 1 instance in which growth of streptococci was obtained under aerobic conditions, similar (nonhemolytic) colonies were obtained on the anaerobic blood agar slant and on the chocolate agar plate in the carbon dioxide jar. The single growth of beta hemolytic streptococci was on an anaerobic plate. The distribution of growth under aerobic and anaerobic conditions and in the carbon dioxide jar is shown in Table II. In 13 of the 14 individuals with positive cultures for streptococci there was an associated growth of lactobacilli.

In this study, no detailed investigation of staphylococci or of diphtheroids was done.

Of the 13 individuals from whom no lactobacilli were grown, 10 had completely sterile cultures. It was impossible to identify any technical errors to explain this.

In 60 (96.8%) of the 62 cultures positive for lactobacilli, growth was obtained on the carbon dioxide plate. In the other 2 instances, growth occurred on aerobic blood agar plates only. Ten of the 60 positive cultures on carbon dioxide plates were accompanied by growth of lactobacilli on the aerobic or anaerobic culture media, or on both (Table IV).

Seventy-one (94.7%) of the direct smears contained large bacilli suggestive of lactobacilli. In 5 instances, however, these rods were

TABLE IV.—DISTRIBUTION OF POSITIVE CULTURES OF LACTOBACILLI ON VARIOUS MEDIA

Media	No. positive cultures of lactobacilli	Per cent of positive cultures
Carbon dioxide plates only	50	80.7
Aerobic plates only	2	3.2
Anaerobic plates only	0	0
Aerobic and anaerobic plates	0	0
Aerobic and carbon dioxide plates	2	3.2
Anaerobic and carbon dioxide plates	6	9.7
Aerobic, anaerobic, and carbon dioxide plates	2	3.2
Total	62	100.0

gram negative and the presumptive evidence of lactobacilli in direct smears may thus be reduced to 88.0 per cent. In all 13 of the cases with negative cultures for lactobacilli, the direct smear showed bacilli consistent with this organism, and by combining information from both cultures and direct smears, there is evidence of lactobacilli in 75 members of the series (100%).

Study of the direct smears for organisms other than lactobacilli was of little value. Cocci and small rods could seldom be identified with assurance. In no instance were cocci in chains noted. The saline suspensions showed motile trichomonads in 2 instances.

2 Relation of organisms to each other In 37 instances (49.3%) lactobacilli only were cultivated. Three cultures yielded other organisms but no lactobacilli and would compose the group usually described as grade III. The conventional grading does not provide for the 10 instances in which no growth was obtained. We have designated this group as grade O in Table III which shows the incidence of the various grades from cultural evidence alone. If presumptive evidence from the smears is combined with the above information, grade O would be eliminated and the 10 cases would be added to grade I while grade III would be reduced to 1 case.

3 Relation of pH to flora In all members of the grade I group the pH was 4.5. The 5 individuals from whom fungi were grown also had pH 4.5. Otherwise grades or specific organisms cannot be correlated with degree of vaginal acidity. Of the 12 individuals with positive cultures for streptococci in which the pH is known, the readings are distributed as follows: 4.5, 6 cases; 5.5, 3 cases; 5.0, 6.5

TABLE V.—TECHNIQUE AND RESULTS OF SMEARS AND CULTURES FOR DOEDERLEIN'S BACILLUS

Investigator	N. of investigations	Media described	Delay in plating	Media used	Atmosphere for culture	Positive cultures Per cent	Positive stained smears Per cent
Lusk and Kaplan	94	no H ₂ O ₂	None	Dextrose broth. Subcultures to blood agar. Lysine decarboxase agar plates.	All aerobic. Also 5 anaerobic	5	41
Thomas	107	Green soap barrier (H ₂ O) and H ₂ O ₂	None	Whey agar plates	Aerobic and Anaerobic	7.5	11.7
Crichton-Smith			1-3 hrs.	1% lactose or glucose hormone agar plus 5% defibrinated rabbit blood	Aerobic		
Wronson	374	N	hr or less	Tomato peptone pyrazinized milk, yeast agar	Under CO ₂	(non-pyrazinized series) (no in pyrazinized series)	Not reported
Lock et al	71	N	1 min. or less	Chocolate agar	Under CO ₂	8.6	24 (corrected) (excl. from neg. rule on smearing lactose 24)

and 7.5 in each. Nine individuals had readings of more than 4.5 distributed as follows: pH 5.0 in 4 cases, 5.5 in 3 cases, 6.5 in 1 case and 7.5 in 1 case.

Seven of these had grade II flora including the ones with pH 6.5 and pH 7.5. Two with grade III flora had pH readings of 5.0 and 5.5 and 1 individual with grade III flora had a vaginal pH of 4.5. No correlation could be made between pH vaginal flora and the number of days since the last menstrual period or until the next expected menstrual period.

4. *Relation of personal cleanliness to vaginal cleanliness.* No satisfactory method of evaluating personal cleanliness could be devised. From a record of the hours since the last bath no correlation could be made with the vaginal flora.

5. *Influence of flora on vaginal secretions.* Although all individuals originally denied any gynecological complaint 27 answered in the affirmative when asked directly if they were aware of any vaginal discharge. From the intermittent character and time of occurrence 6 were definitely and 7 possibly traced to the premenstrual phase of the menstrual cycle. The remaining 14 had a continuous slight discharge. Four of the 27 had negative cultures, 12 had grade I, 9 had grade II and 2 had grade III flora. Of the 5 individuals harboring fungi 3 had no discharge. This included the individual who harbored both *Cryptococcus* species and *Candida Krusei*. Two

positive cultures for *Candida stellatoidea*, had a slight discharge described as thin, white nonirritating and odorless. In the 2 individuals harboring trichomonads no vaginal discharge had been noted.

DISCUSSION

Our method of growing lactobacilli in an atmosphere of 10 to 20 per cent carbon dioxide is not new but its effectiveness has not been emphasized in previous writings (8,10, 13, 22, 25, 26). Further work seems indicated to determine whether it is the chocolate agar, the carbon dioxide atmosphere, the associated reduced oxygen tension, the choice of subjects, method of taking cultures or the technique in plating the material that accounts for our relatively high incidence of positive cultures (Table V). A discrepancy between stained smears and cultures of vaginal lactobacilli is not unusual as shown in Table V.

Our introduction of the term grade 0 flora is possibly superfluous since stained smears furnished evidence that the negative cultures represented a failure to cultivate organisms which were present. This grouping however places such organisms into a separate category with different cultural characteristics from those which were cultivated. Thus 13.3 per cent of our present series of individuals harbored organisms which did not survive the usual method of culture. This fact assumes importance compared with an incidence

in our laboratory of only 3 per cent negative vaginal cultures from patients with various gynecological complaints. Further attempts at isolation and identification of the organisms of grade O flora seem indicated.

Our failure to correlate the higher pH range with grade III flora is in agreement with the work of Weinstein (23). It is also interesting to note that a combined lactobacillus-streptococcus flora is associated with both high and low pH. This is contrary to the classical conception that these organisms each grow in a pH range which the other cannot tolerate. Our finding lactobacilli in the vaginas of pH of about 7.0 supports Weinstein's (23) contention that there is no direct correlation between the presence of lactobacilli in the vagina and its degree of acidity.

It is interesting to note that the streptococci were almost all microaerophilic or anaerobic. This fact raises a question as to how often such organisms may be lost if cultures are not planned to take into account adaptation to special environment in the various body cavities.

Although *Candida stellatoidea* and *Candida Krusei* are believed to be causes of vulvovaginitis (5, 12) the 4 individuals who harbored these yeasts in the present study had no pruritus and only 2 had a slight discharge. A growth of *Cryptococcus* species is usually considered to be due to air contamination (6) but in this instance may represent a true vaginal saprophyte since several colonies developed both on Sabouraud's medium and on blood agar.

Several features of this study are open to criticism. The series is short. The individuals were not followed with repeated cultures. The method of determining the pH was crude. The extent to which *Staphylococcus albus* and the streptococci were respiratory contaminants is uncertain. No attempt was made to demonstrate the organisms requiring special methods. It might be argued that spirochetes, tubercle bacilli, pleuropneumonia-like organisms (3, 14), or other rare inhabitants of the vagina were missed.

All techniques for obtaining vaginal cultures are unsatisfactory, and it is doubtful if a real vaginal culture has ever been obtained. Harris and Brown (9) devised a method which

in their hands was satisfactory. They used a tube within a tube, the outer one wearing a rubber cuff which was protected by protrusion of the inner tube. However, Adair and associates have shown that the Harris-Brown technique as well as several other methods failed to prevent contamination from organisms of the perineal region. Our method seemingly obviated this objection since the device used did not touch the introitus or even the vagina for a distance of about 1 1/4 centimeters. Thus ascent of any organisms would be from the lower vagina and not from the vulva. Our method is easily applied to nulliparous individuals but might be unsatisfactory in the presence of large cystoceles or rectoceles.

If vulvar contamination occurred in our present study it would chiefly affect the statistics in regard to the occurrence of staphylococci. In regard to possible contamination from the perineum it is interesting to note that no culture was positive for *Streptococcus fecalis* and that coliform organisms were recovered in only one instance.

SUMMARY

A survey was made of the vaginal flora in 75 normal unmarried young women.

Culture media and methods were those used in the ordinary bacteriology laboratory for routine cultures plus chocolate agar carbon dioxide for lactobacilli.

Lactobacilli were cultured from 82.6 per cent of the subjects. This was a higher yield than any that has been recorded by previous workers.

Stained smears furnished presumptive evidence that lactobacilli were present in 100 per cent of the subjects.

The flora was classified according to the classical grades: 49.3 per cent fall into grade I, 33.3 per cent into grade II, and 4.0 per cent into grade III. In 13.3 per cent of the subjects the cultures were sterile (grade O).

Grade II and grade III flora cannot be correlated with the vaginal pH. In all instances grade I flora was associated with vaginal pH 4.5.

Besides lactobacilli, other organisms obtained on culture were diphtheroids, Staph

ylcococcus albus, streptococci colliform organisms, and yeast like fungi

All the streptococci grew under carbon dioxide or anaerobically

Ninety six and eight tenths per cent of the lactobacilli grew on chocolate agar in carbon dioxide jars.

CONCLUSIONS

1 Healthy unmarried young adult females usually harbor lactobacilli within the vagina about one-half also harbor other organisms, chiefly diphtheroids, Staphylococcus albus, and streptococci.

2 Lactobacilli can exist in vaginas ranging in pH from 4.5 to 7.5

3 Cultivation of vaginal lactobacilli on chocolate agar in a carbon dioxide jar gives the most satisfactory yield reported to date but cannot be considered an ideal method.

4 Vaginal streptococci are adapted to a low oxygen environment.

INFLAMMATORY CARCINOMA OF THE BREAST

ALFRED C MEYER M.D., MALCOLM B DOCKERTY M.D., and
STUART W HARRINGTON M.D., Rochester Minnesota

THAT certain malignant lesions of the breast may simulate inflammatory lesions clinically has long been a matter of common knowledge to clinicians and pathologists. Although clinically these lesions do not present the usual picture of carcinoma of the breast and often have been mistaken for inflammatory lesions pathologically they represent a very virulent type of cancer. They have been described by various writers under a great many different names. To denote its resemblance to inflammation the condition has been called mastitis carcinomatosa (27,38) carcinomatous mastitis (10) carcinoma mastoides (35) erysipeloid carcinoma (4 6 16 20 26 29 30 32 33) mammary carcinoma with cutaneous carcioma of erysipelatodes type (8) and inflammatory carcinoma (13 15 22, 36 41). It has also been called brawny breasts (1) acute cancer (3 15 19 21 23 25 31) telangiectatic carcinoma (9 37 40) and subepidermoidal carcinoma of the breast (11, 12).

The purpose of this study was to describe and classify this type of disease to investigate its pathologic characteristics and to correlate its clinical manifestations with its pathologic characteristics.

MATERIALS AND METHODS

Approximately 7,000 consecutive cases of malignant lesions of the breast encountered at the Mayo Clinic from 1933 through 1945 were reviewed. All cases in which inflammatory signs such as redness and edema were manifested or in which inflammatory disease had been diagnosed before the malignancy of the lesion was recognized were selected for further study. It became apparent that redness and

edema were frequently present in cases of malignant lesion of the breast in which the breast was enlarged and in which the lesion was diffuse rather than localized. These cases were, therefore added to the study.

After discarding those cases in which the redness and edema were localized and obviously due to early necrosis and infection from invasion of the skin 74 cases which seemed characteristic were finally selected. In 61 of these radical mastectomy had been performed in 2 simple mastectomy and in 2 biopsy. Tissues obtained in these 65 cases were studied in detail including multiple blocks cut from all parts of the breasts which had been removed. Paraffin sections were made and stained with hematoxylin and eosin.

For purposes of orientation and control 50 additional cases of noninflammatory carcinoma of the breast were subjected to a similar examination.

CLINICAL FINDINGS IN 74 CASES

Incidence. Of approximately 7,000 cases of malignant lesion of the breast 74 were judged to be characteristic of the so-called inflammatory carcinoma type. This is an incidence of about 1 per cent.

Age and sex. The youngest patient in the series was 32 years old and the oldest was 72. The average age was 52.6 years. All of the patients were women.

Side affected. It was interesting that the left breast was involved almost twice as frequently as the right. In the total of 74 cases the lesion affected the left breast primarily in 46 the right in 28.

Bilaterality. At the time of initial examination at the clinic 2 patients already had bilateral inflammatory carcinoma and another had scirrhus carcinoma of different grade in the breast opposite the one which contained the inflammatory carcinoma. In 6 cases carcinoma subsequently developed in the reman-

Abstriment of thesis submitted by Dr. Meyer to the Faculty of the Graduate School of the University of Minnesota in partial fulfillment of the requirements for the degree of M.S. in Surgery.

Fig. 1 Symmetrical enlargement of the breast in the presence of inflammatory carcinoma. The first diagnosis, which had been made by a physician elsewhere, had been fungus infection.

Fig. 2 Diffuse enlargement and discoloration of the breast in case of inflammatory carcinoma. This patient had been told by her physician that she had mastitis and she had been treated with estrogen.

ing breast and 1 patient had undergone radical mastectomy for Paget's disease 2 years previous to her examination at the clinic.

Altogether 10 patients or 13.5 per cent of the group eventually had bilateral carcinoma of the breast. The time interval between the appearance of disease in the first and second breasts varied from 4 months to 7 years with an average of 2 years. In no instance did the carcinoma appear to occur simultaneously in both breasts.

Pregnancy and lactation. Twenty-four of the 74 patients had never been pregnant. One had been pregnant a short time before admission and was still lactating.

Duration of symptoms. The average duration of time before these patients came to the clinic after first noticing something wrong with their breasts was 7 months. The longest period of time was 5 years and the shortest 8 days.

Signs and symptoms. As implied by the descriptive names previously given to this condition its clinical signs are largely those of inflammation. So much did the condition in some of these breasts resemble an inflammatory process that it was erroneously and perhaps tragically treated as such. It is not surprising that in 14 (18.9 per cent) of the 74 cases, the condition was diagnosed inflammatory disease before its true carcinomatous nature was discovered.

The cardinal symptom of carcinoma of the breast is a lump, but in these cases a lump was

noticed by only 62 per cent of the patients. Physical examination commonly revealed diffuse induration extending through much or all of the breast. In 45 per cent of the cases the tumor could not be palpated when the patient was examined at the clinic and in the others it was poorly demarcated.

Most carcinomas do not cause an increase in the size of the breast. Inflammatory carcinoma on the contrary frequently enlarges the breast. Enlargement of one breast was the patient's first inkling of trouble in 6 cases (8.1 per cent). On examination at the clinic the affected breast was described as being enlarged grossly in 38 cases, a little more than half the total number. The enlargement consisted not of a tumorous protrusion but rather of a symmetrical increase in the size of the whole breast (Figs. 1 and 2).

The skin of the breasts was red or edematous or both as if there was infection beneath. The redness varied from a rosy hue over the center or lower part to an angry red or violaceous color of the whole breast, sometimes even extending over the thoracic wall and to the axilla. Likewise the edema varied from slight puffiness of the skin to sudden thickening which pitted on pressure. Both the redness and edema were intensified when the patient stood for a long time and receded when she lay down. The lower dependent portion of the breast was more often and more severely affected. Seventy-three per cent of the breasts were described as being red and 78 per cent

Fig. 3. Massive diffuse involvement of entire breast. Note thickening of skin.

Fig. 4. Diffuse growth in strands throughout the breast. The carcinoma can be seen grossly extending along the suspensory ligaments of Cooper. The thickening and edema of the skin are apparent.

were edematous on physical examination (Since these data were taken from records which in some cases were incomplete it is felt that the incidence of redness and edema was probably higher perhaps nearly 100 per cent.)

It is true that redness and edema occur over a carcinoma which is infiltrating the skin and causing necrosis and ulceration. These however result from true inflammation and are not to be confused with redness and edema caused by inflammatory carcinoma.

Pain was a frequent symptom. Fifty three per cent of the patients had pain at some time during the course of their disease, and in 26 per cent of the cases pain was the first symptom noticed.

Clinical examination revealed attachment of the skin to the underlying malignant tissue in 44 cases (59.4 per cent).

The nipple was noted as being retracted in 54 per cent of the cases.

Despite extensive involvement of the breasts in many cases there were only 2 instances of ulceration of the skin. It occurred very late in a case of bilateral massive involvement which was treated only with roentgen rays. In the other case an ulcer of a deeply retracted nipple was present.

PATHOLOGIC FINDINGS IN 65 CASES

Gross examination. The affected breasts were all large and the discoloration and edema observed clinically were apparent in the specimens.

Skin.—On cut section the skin was found to be remarkably thickened and edematous

measuring from 2 up to 8 millimeters in thickness and averaging about 4 millimeters.

In none of the specimens was the skin destroyed by the growth. Even in those breasts in which the tumor seemed to occupy the entire substance of the breast the skin remained intact over it. In the 2 aforementioned exceptions pathologic examination could not be carried out in the case in which only irradiation was given and in the other the ulcer involved only the nipple.

Tumor.—In general the outstanding characteristics of the growth were its diffuseness and its extensiveness. In 28 cases (43 per cent) the growth was so widespread that there was no evidence of localization whatsoever (Figs. 3 and 4). Instead there were strands of diffusely growing carcinoma throughout the breast. Sometimes the clusters of malignant cells did not seem to be connected with one another and in 3 such instances the clusters were so widely separated the growth was classified as multicentric. In 16 specimens or 24.6 per cent there was a diffuse growth in the breasts but a localized tumor could also be recognized. In 19 cases or 29.2 per cent a localized tumor without diffuse extension was present.

When there was a localized tumor in most instances it was very large. The size varied however from 2 by 1.5 by 1.5 centimeters to 12 by 11 by 7 centimeters. The average size was 6 by 5 by 5 centimeters.

Among the growths which were well enough localized to allow specification of their positions in the breasts, 17 occupied the center of the breast, 8 were so large as to occupy practi-

Fig. 5. Carcinoma spreading through the lymphatics in suspension ligament of Cooper (hematoxylin and eosin X35).

cally the entire breast 6 were in the upper outer quadrant and there was 1 each in the lower inner quadrant, upper half lower half and outer half.

Lymph nodes—The axillary lymph nodes were enlarged and firm in all cases but they did not differ in appearance from those of the usual case of carcinoma of the breast with gross metastasis to the axillary lymph nodes.

Microscopic examination The massive involvement noted grossly was confirmed on microscopic examination. The carcinoma was widespread and was found to be growing in all directions from the main masses of tumor tissue. Especially prominent were the ligaments of Cooper (Fig. 5) in which the cancer apparently was spreading by way of the lymphatic vessels.

Lymphatics—In the course of microscopic examination as the ligaments of Cooper were followed to the skin the subepidermal lymphatics were encountered spreading peripherally. In 80 per cent of the cases these lymphatics contained carcinoma cells and this was a characteristic feature of the disease. These lymphatics lay at the level of the sweat and sebaceous glands and ran parallel to the surface of the skin (Fig. 6a and b). In some breasts every subepidermal lymphatic seemed plugged with cancer cells (Fig. 6c) while in others many sections had to be cut before involved lymphatics could be found. In 13 breasts or 20 per cent carcinoma cells were

TABLE I—POSTOPERATIVE SURVIVAL OF PATIENTS WHO HAD INFLAMMATORY ADENO-CARCINOMA OF THE BREAST

	Years				
			3	5	
Patients followed	30	40	40	42	42
Patients known to have died	16	32	43	44	46
Patients known to have been alive	14	7	7		
Percent known to have been alive	68	35	24	6	

not found in the subepidermal lymphatics, but in 4 of these and in the specimens removed for biopsy in the 2 cases in which the lesion was inoperable carcinoma was found in the deeper lymphatics. Carcinoma cells were found in the lymphatics in 86 per cent of the cases in which surgical exploration was carried out.

Blood vessels—The subepidermal capillaries, which run in the same plane as the lymphatics were generally distended and engorged with blood. Cancer cells were found there in only 2 cases, but blood vessels containing carcinoma cells were found deeper in the breast in 13 instances making a total of 15 cases or 23 per cent in which intravascular spread occurred (Fig. 7a).

Skin—The edema of the skin visible grossly was found on microscopic examination to be mostly in the dermis, through which ran the subepidermal lymphatic and blood vessels (Fig. 6b and c). The carcinoma cells were found in the lymphatics and blood vessels of the skin but did not infiltrate the skin directly. There were no cancer cells in the epidermis, nor was there necrosis or abscess formation.

Inflammation—Lymphocytes and plasma cells were present in abundance at the margins of the carcinoma, but no more so than at the margins of the usual carcinoma of the breast. In the ligaments of Cooper and at the level of the subepidermal vessels there was an increased number of perivascular lymphocytes and plasma cells (Fig. 7b). In 28 cases (43 per cent) the increase was more marked than is usual in cases of carcinoma of the breast. It was impossible to correlate either the gross or microscopic extent of the disease with the number of lymphocytes and plasma

c

cells. Breasts in which every subepidermal lymphatic seemed plugged with carcinoma did not necessarily display greater perivascular reaction than those breasts in which the presence of carcinoma cells was comparatively infrequent. Nor was the amount of redness and edema related to the number of lymphocytes and plasma cells present.

In no instance was there evidence of acute inflammation or suppuration.

Grade of malignancy.—In all cases the carcinoma was highly anaplastic. Graded on the basis of 1 to 4 by Broders' method in which in grade 1 the cells are most differentiated and in grade 4, least differentiated. 88 per cent of the lesions were graded 4 and 12 per cent were graded 3. All were adenocarcinomas and 5 were mucus producing. Axillary nodal metastasis was present in 100 per cent.

Characteristics of growth.—Nothing distinctive could be found in the individual cells nor in the architecture of the growth. It was, however, in the manner of its spread that this carcinoma manifested its individuality. Rather than growing as a directly infiltrating mass, it disseminated itself through lymphatics and blood vessels.

TREATMENT AND PROGNOSIS

Sixty three of the 74 patients underwent mastectomy. In 61 cases radical mastectomy was performed and in 2 simple palliative mastectomy. All but 1 of the patients were given postoperative irradiation. In 10 of the 11 cases in which the condition was inoperable because of obvious spread beyond the limits of surgical excision, roentgen therapy was given.

Fig. 7. Capillary spread of the carcinoma (hematoxylin and eosin $\times 350$). b, Marked lymphocytic reaction around carcinoma cells in lymphatics (hematoxylin and eosin $\times 40$).

It was possible to follow up 7 of the patients who had inoperable lesions. None of them lived more than 3 years. Of the group that received surgical treatment some were treated too recently for appraisal and it was not possible to follow up a few of the others. Some were known to have survived several years and then further information concerning them could not be obtained. Information concerning survival is given in Table I.

There was no appreciable difference in prognosis in those cases in which the lesion was graded 3 and in those in which it was grade 4—an observation emphasizing the widespread nature of the disease.

Recognizable metastasis aside from that to the axillary and supraclavicular nodes was known to have developed in 42 of the 74 cases studied. By far the most frequent site of metastasis was the skin (54 per cent of 41 cases). In 20 of the 23 cases in which the lesion metastasized to the skin it metastasized to the skin of the thoracic wall and in one each to the arm and axilla on the same side and to the abdominal wall on the side opposite the lesion. In 2 instances there were recurrences in the scar left after previous mastectomy. Other common sites of metastasis were bone (38 per cent) thorax, including

lung pleura and mediastinum (33 per cent) and the opposite breast (21 per cent) (Fig. 8). The total of the percentages equals more than 100 per cent since in several cases there was more than one site of metastasis.

COMMENT

The age incidence for inflammatory carcinoma in our series seemed to be about that for carcinoma of the breast in general. The average age of the patients was 56.2 years, which is similar to the average age (51.3 years) which Harrington (17) found in a study of 6195 consecutive cases of carcinoma of the breast at the Mayo Clinic. Although all patients in this series were females Schreiner and Volavsek and Rotter described occurrence of inflammatory carcinoma of the breast in the male.

Some writers including Boyd, Schumann, Volkman, Da Costa, Gronwald and Ibarbia and Bessone have suggested that the occurrence of this type of carcinoma is related to pregnancy and especially to the postpartum period. Others (Lee and Tannenbaum, Taylor and Meltzer and Dawson and Shaw) did not believe that inflammatory carcinoma was particularly prone to occur during this period. Learmonth emphasized the mistake in coo-

fusing the rapidly growing carcinomas in younger women with true inflammatory carcinoma. Among the 74 cases studied pregnancy and lactation did not appear to have any relationship to the development of inflammatory carcinoma.

The high incidence of bilateral involvement in cases of inflammatory carcinoma has been noted by Dawson and Shaw, Ibarhia and Bessone, Bloodgood, Taylor and Meltzer, Weber (39), Rasch and Brackertz. In 13 per cent of our series bilateral carcinoma of the breast developed. This is appreciably more than the 6 to 8 per cent Harrington (18) found in a review of 6261 cases of all types of carcinoma of the breast.

Among those who have studied the pathology of inflammatory carcinoma, there has been much controversy as to whether this type of malignant lesion spreads through the lymphatics or blood vessels. Leitch, Fischer, Camiel and Bolker, Orbach and Schreiner and Volavsek believed that it spread through the lymphatics while Küttner, Freeman and Lynch, Nanta and Salvador, Rasch and Van Vonn found it spreading in the blood vessels. Still others (Lee and Tannenbaum, Ibarhia and Bessone, Weber (39), Dawson and Davie, Dawson and Shaw, Pfahler and Case and Nix) found the cancer invading both lymphatic and blood vessels. Extensive examination of multiple sections cut from the breasts removed in our cases demonstrated spread through both blood and lymphatic vessels although predominantly through the latter. It is the peculiar propensity of this type of malignant lesion to spread toward the skin and through the subepidermal lymphatics and this propensity gives it some of its unusual clinical attributes. The presence of carcinoma in the lymphatics of the skin, many of which are blocked, prevents drainage of lymph and causes edema of the skin. Generalized lymphatic involvement throughout the breast produces stasis of lymph and later enlargement of the entire breast.

It is quite likely that stasis also accounts for the redness and discoloration of the breast. Like the edema, the redness tends to disappear when the patient is lying down. Extensive cancer plus inadequate lymphatic drainage produces increased pressure within the

Fig. 8. Evidence of metastasis to the thoracic wall and the opposite breast.

breast and the resultant passive hyperemia. The presence of an increased amount of blood especially in the subepidermal region leads to redness and blueness of the skin. When the patient is in the recumbent position the effect of gravity somewhat reduces the amount of stasis and modifies the circulatory findings.

In no instance was there either clinical or pathologic evidence of infection to account for the inflammatory signs in our series of cases. At microscopic examination lymphocytes and plasma cells were often found in the vicinity of the cancer, but no more than in comparable carcinomas without clinical signs of inflammation. Clumps of lymphocytes were also found in the subepidermal tissue as previously described by Learmonth, Ewing (according to Lee and Tannenbaum) and Leitch. The finding of these clumps may indicate that stasis of lymph or possibly a reaction to some irritant product of the carcinoma had occurred.

All observers who have studied inflammatory carcinoma have been impressed with its poor prognosis. Some writers (Lee and Tannenbaum, Geschickter, Pack and Livingston and White) have felt that palliation is the only hope and that irradiation is the best therapy. Orbach, Leitch, Bloodgood and Learmonth, however, reported occasional excellent results of surgical treatment. In our series surgical treatment was employed in all cases in which the lesion had not obviously spread beyond the limits of excision. The fact that 3 patients survived for 5 years after operation would seem to justify this type of therapy.

SUMMARY

In 74 (1 per cent) of approximately 7000 cases of malignant lesion of the breast, the

diagnosis was inflammatory carcinoma because of characteristic clinical features which simulated those of inflammation. The disease was found to occur to the same general age group as carcinoma of the breast and there was no particular correlation with pregnancy or lactation. The incidence of bilateral malignancy was two times that noted in comparable cases of the usual carcinoma of the breast. The left breast was affected primarily nearly twice as frequently as the right. On examination both breasts were large and often the involved one had become bigger than its mate. The skin over the breasts was red or edematous or both and palpation frequently revealed diffuse infiltration rather than a localized tumor. The axillary nodes were involved in all cases.

Pathologically the lesions were diffuse high-grade adenocarcinomas, which frequently involved the lymphatics and occasionally the blood vessels. Characteristically the cancer spread through the subepidermal lymphatics. There was no evidence of bacterial infection and ulceration of the skin was extremely rare. The inflammatory appearance was apparently due to blockage of the lymphatics by cancer cells and the resultant vascular phenomena.

Prognosis for life is poor but 3 patients lived more than 5 years after operation and 1 was alive 9 years after operation.

The common sites of metastasis were the thorax bone the opposite breast and the skin. Occurrence of metastasis to the skin was especially frequent, having been present in 55 per cent of the cases in which metastasis was known to have occurred.

THE EARLY CLOSURE OF CONSTANTLY CONTAMINATED INFECTED WOUNDS WITH THE AID OF URETHANE- PENICILLIN MIXTURES

CHESTER W HOWE, M.D. F.A.C.S. Boston, Massachusetts

ABSCESSED, undermined postoperative wound infections are occasionally encountered by the surgeon in spite of improved techniques and antibacterial therapy. If the incision is near the anus or has a colostomy in or adjacent to it, one is confronted with the problem of constant fecal contamination (Fig 1). These wounds are complicated by prolonged hospitalization, painful dressings, loss of protein, and hernias. Frequently the fear of evisceration causes temporization in the usually accepted principle of adequate open drainage. It is the purpose of this preliminary report to show that such wounds can be opened widely surgically closed, and satisfactorily healed within a short period of time in spite of constant contamination.

It has been our observation that infected wounds treated with wide open drainage and subsequent healing by second intention progress much more rapidly and favorably than do those which are treated by means of conservative catheter irrigations or drainage through small openings.

The war literature has clarified and emphasized certain principles of reparative surgery as applied to battle injuries. In general, the accepted treatment for all wounds is a two stage operation consisting of débridement and closure. The optimal time for this closure begins on about the fourth and ends on approximately the tenth day. Early in this period muscle and fascial planes can be sutured but beyond the fourth day the feasibility of

anatomic layer closure diminishes and the need for through and through sutures under cutting and wound excision increases (1). Invasive infection calls for drainage, excision of devitalized tissue, chemotherapy, and moist dressings (2). The severity of the infection dictates the time of closure. Decision to close a wound should be based on its gross appearance. Experience has shown that decision to close a wound based on bacteriological study is impractical, failure having followed the closure of sterile but dirty wounds while 'clean' wounds healing by first intention after delayed closure may show a profuse bacterial flora (2). Thus closure and not sterilization is the primary objective in wound management. Lyons stated that, Suppuration of a wound is believed to be due more to the presence of a pabulum of wound protein than to any specific bacterial virulence. The presence of devitalized tissue prevents or delays the action of antibacterial agents and calls for prompt débridement. It is obvious that surgical débridement is more rapid and effective than chemical methods.

The above outlined principles which have proved successful in the management of war injuries and in the closure of decubitus ulcers have not been widely applied to postoperative wound infections. Although it is not possible to sterilize a wound that is constantly being recontaminated by feces it has been possible with the use of proper surgical measures and the aid of chemotherapeutic and antibiotic agents to convert it into a clean wound and to effect an early surgical closure in the majority of instances in this small series.

Many of the infections reported here are distinguished by the fact that the abscess is discovered after the fourth day and involves the full extent of a closed surgical wound down to the peritoneal layer. A colostomy in or

Presented in part in the Forum on Fundamental Surgical Problems before the Thirty Third Clinical Congress of the American College of Surgeons, New York, September 8-13, 1947.

This study was aided by the President's Fellowship of Brown University.

Fig. Infected undermined postoperative wound with retracted colostomy pouring feces into it.

adjacent to the wound may be a constant source of recontamination. The patient is in the older age group and has been debilitated by malignant or chronic disease and an operation. The danger of evacuation is imminent. Invasive infection is often present in spite of previous antibiotic and chemotherapy and calls for the application of moist dressings. For this purpose we have instituted the use of a 10 per cent solution of urethane containing 1,000 units of penicillin per cubic centimeter.

The limited rôle of chemotherapy in the management of wounds has been emphasized and local chemotherapy has been condemned (10). There are many reasons to explain the failure of topical therapy of infected wounds. Among these are the ineffectiveness of the agent in the presence of pus and devitalized tissue, the formation of penicillinase by certain gram negative organisms, the local trauma incident to topical therapy and the inability of available antibacterial agents to sterilize a wound. On the basis of accumulated experience in large series of cases the local use of the sulfonamides in open wounds has been abandoned (3, 11). It is questionable whether a blanket condemnation of all local chemotherapy is justifiable based on experience with the relatively few antibacterial agents that have had adequate clinical trials. Certain agents

such as activated zinc peroxide, normal saline, and hypochlorite solutions are of established value under certain conditions. Few antibacterial agents have had adequate evaluation based on large series of cases comparable to the studies on penicillin and the sulfonamides conducted by the Subcommittee on Surgical Infections and Burns of the National Research Council. There are instances in which systemic antibacterial therapy is impossible or unjustified in ambulatory patients with small lesions. Some form of local therapy is indicated in these cases. Because of inadequate blood supply or scar tissue barrier it is often impossible to secure effective concentration at the site of the lesion by use of a systemically administered drug. Encouraging reports on the use of local antibiotic and chemotherapeutic agents have recently appeared in the literature (5, 6, 12).

The proper treatment of surgical infections demands that the selection of the antibacterial agent be based on the sensitivity of the organisms present in the wound which is being treated. A number of agents are now available each with its own specific indications and contraindications. It is not necessarily a requirement that an antibacterial agent should sterilize a wound to establish its value. It is possible that some of the antibacterial agents now being studied will assume a useful though limited rôle as topical agents in the fight against infection. In cases in which moist dressings are indicated, especially in the presence of frequent fecal contamination, it would seem rational to use a solution containing antibacterial agents capable of modifying the bacterial flora and helping to hold it in check, provided one is available that is not damaging to tissue.

We first used urethane as an antibacterial agent in 1944 after Weinstein and McDonald demonstrated in vitro that this drug was a potent bactericidal agent for gram negative organisms (14). Earlier this year a study of 39 urethane treated patients was reported and the highly specific action of this drug against gram negative organisms was substantiated when it was applied topically to infected wounds in man (8). This specificity suggested that urethane might be advantageously combined with penicillin for theoretically it should

stop the formation of penicillinase by attacking the gram negative organisms and thus enhance the action of penicillin against the gram positive organisms in the same wound. A combination of bacteriostatic quantities of urethane with penicillin has since been shown to bring about a complete suppression of the growth of mixed cultures of *Staphylococcus aureus* and of *Escherichia coli*. No inactivation of penicillin by the urethane or of urethane by the antibiotic agent could be demonstrated (13).

Chemical observations and laboratory data indicate that the occasional gastrointestinal symptoms accompanying urethane therapy are not due to organic toxic changes (7). Over 60 patients have been treated with topical urethane solution either alone or in combination with sulfanilamide or penicillin. Of the first 39 cases reported, 5 patients were treated with 10 per cent urethane solution, 2 with 20 per cent urethane solution and 32 with a combination of 10 per cent urethane and 1 per cent sulfanilamide. We abandoned the use of sulfanilamide in the mixture because the slight synergistic effect demonstrated *in vitro* seemed of no significance clinically and the bacterial flora showed as good a response by using urethane alone (8). We are now using the urethane penicillin mixture unless the culture shows a pure gram negative flora. The 17 patients whose cases are reported were treated with a solution of 10 per cent urethane containing 1,000 units of penicillin per cubic centimeter with the exception of one patient (Case 1) who was treated with 10 per cent urethane alone and another (Case 12) who was treated with a solution of 10 per cent urethane and 1 per cent sulfanilamide. Eight of the 17 patients had an open colostomy in or adjacent to the wound.

METHOD

On discovery of the infection wide open drainage culture and débridement are done in the operating room. Abdominal wounds are opened down to the peritoneal layer and all devitalized tissue is excised. Fine steel wire sutures are placed and left untied to be secured in the event of evisceration. Two small catheters are anchored into the wound which is packed with gauze. Surrounding skin

Fig. 2. Case 1. a. Infected postoperative abdominal wound (Miles operation). Note the colostomy presenting in the wound and the intact peritoneum. Wire sutures are in place to be secured in the event of evisceration. Picture taken 6 days after drainage of abscess, débridement of slough and necrotic fascia and constant 10 per cent urethane soaks. The wound is clean and healthy. Drain communicates with the perineal wound beneath symphysis pubis. b. Wound surgically closed around the colostomy 13 days after débridement and urethane therapy and healed as by primary intention. We now believe that such wounds can be closed on the fourth to sixth day.

areas are covered with vaseline strips. An outer sterile dressing is covered with waxed paper. Paregonic or deodorized tincture of opium is given to check colostomy discharge if necessary. Systemic antibacterial therapy is continued as indicated. Urethane penicillin mixture is injected into the catheters every 2 hours in amounts sufficient to keep the wound constantly wet without soaking the surrounding skin. Packs are changed promptly when gross fecal contamination occurs, mask and sterile gloves are used. Otherwise the wound is inspected on the third to the fifth day depending on our estimation as to when it will be ready. This estimate is based on its appearance at the time of débridement. In order to be ready for immediate closure the inspection should be carried out on the operating table to avoid the possible contamination entailed in a dressing on the ward. If the appearance of the wound is not satisfactory further débridement may be indicated, a fresh dressing is applied and treatment is continued.

Fig. 3 Case 1. a, Infected undermined abdominal wound with adjacent open draining colostomy. About 5 ounces of thick pus has just been evacuated. b, Wound opened widely in operating room. Debridement to be done.

c, Wound clean and surgically closed after 8 days of treatment with moist dressing of 10 per cent urethane solution containing 1,000 units of penicillin per cubic centimeter. d, Primary healing.

The next inspection is carried out after 3 or more days of continued therapy depending on the condition of the wound at the time of the first inspection.

Wounds so treated remain clean, red, soft and free from green pyocyanous pigment. Closure is usually done under light pentothal anesthesia. If the infection has been discovered early and drainage and débridement promptly carried out, it is sometimes possible to do a layer closure after ample freshening of skin margins. Beyond 4 days following drainage and débridement, the wound is usually clean but rigid in which case it is excised. It is seldom possible to do a layer closure after excision. Fine through-and-through steel wire sutures are placed about $\frac{3}{8}$ inch apart and alternate wires may be tied over space obliterating gauze rolls (Fig. 4c). The skin is approximated with additional silk sutures. Originally 2 No. 10 F perforated soft rubber catheters were led out through the wound extremities to allow drainage and through which to instill urethane-penicillin mixture for 2 or 3 days. This measure has lately been abandoned. If a colostomy is present, a small portion of the wound around it is left unclosed and is packed with gauze saturated with urethane-penicillin mixture.

The following brief case reports are illustrative.

CASE 1 (Fig. 3). A 50-year-old male had a palliative Miles operation for cancer of the rectum on December 17, 1946. Following operation he was given penicillin 50,000 units every 3 hours for 13 days. On the twelfth postoperative day a serious wound infection was detected. A large abdominal abscess connected with the perineal wound beneath the symphysis pubis which was the site of a low grade osteomyelitis. The incision was opened widely down to the peritoneal layer, debrided, packed, and treated with constant 10 per cent urethane soaks for 13 days. Culture taken at the time of débridement grew out, *Escherichia coli*, *Bacillus mucosus*, *Proteus morgani* and nonhemolytic streptococci. Adequate supportive therapy in the form of blood transfusions, intravenous fluids, amino acids, and vitamins was given. Intramuscular penicillin therapy was discontinued because of development of sensitivity (arthritis). On the seventh day of treatment when the wound was clean and pink the supply of urethane ran out and saline solution was substituted. The following day the wound was lined with a pyogenic membrane and the dressing was green with pyocyanous pigment, but reverted to its clean pink color within 24 hours after returning to urethane treatment. The discharge from the colostomy which opened directly into the wound (Fig. 3a) was kept at a minimum by giving deodorized tincture of opium minims 10 by mouth 4 times a day. On the thirteenth day the wound was closed by excision and undercutting, and with through-and-through fine steel wire sutures. Culture at the time of closure yielded *Pseudomonas pyocyanus*, *Aerobacter aerogenes*, diphtheroids, enterococci, *Clostridium welchii* and pseudotetani. A drain down into the perineal space was led out just above the symphysis pubis. It was removed by the seventh day and its site soon closed over. The wound healed per primam (Fig. 3b).

Fig. 4. Case 6. a, Infected postoperative abdominal wound following drainage of an obstructing appendiceal abscess and ileostomy. Kelly clamp indicates ileostomy discharging into and digesting tissues. Peritoneum is intact. b, Wound opened and debrided. Catheters for instillation of urethane-penicillin mixture are in place and gauze pack will be inserted. Attempted ileostomy closure failed. c, Wound surgically closed around ileostomy after 4 days of treatment with 10 per cent urethane solution containing 1,000 units of penicillin per cubic centimeter. Alternate fine steel wires are tied over space obliterating gauze rolls. d, Blood-cotton pack (3) controlling ileostomy discharge is in place. Wound healed by primary intention.

Such patients usually require weeks of hospital care and dressings. Our present belief is that this wound could have been successfully closed on the fourth or fifth day. The development of suppuration when saline solution was substituted for urethane and its reversion to its former clean state after the reinstitution of urethane therapy are evidence of the beneficial action of the drug in this case.

CASE 2 (Fig. 3) A 64 year old male with mild controlled diabetes not requiring insulin had an infected abdominal wound discovered 11 days after an abdominoperineal sphincter preserving "pull through" operation for cancer of the rectum, and 4 days after an open transverse colostomy done because of retraction of the perineal segment of bowel. On April 28, 1947 the wound was opened widely down to the peritoneal layer and a meticulous débridement was done. Cultures revealed *Escherichia coli* and *Proteus vulgaris*. Two catheters were led out through the extremities of the wound which was lightly packed with gauze. A solution of 10 per cent urethane containing 1,000 units of penicillin per cubic centimeter was injected into the catheters every 2 hours in sufficient quantity to keep the packs constantly wet. Deodorized tincture of opium minims 10 three times a day was given by mouth. On the eighth day of treatment $\frac{3}{4}$ inch of skin and subcutaneous tissue was excised from the wound margins. The fascia was approximated with interrupted chromic catgut and the wound was closed with through-and-through fine steel wire. The skin was further approximated

with black silk. Culture taken at the time of closure yielded the same organisms and the wound was clean and healthy in appearance.

One catheter was led out of the upper end of the wound through which 10 cubic centimeters of urethane penicillin mixture was instilled every 3 hours for 3 days after which the catheter was removed. The patient received parenteral vitamins B, C and K. Before operation his blood volume studies showed a deficit of 18 cubic centimeters. He received one blood transfusion during his original operation and his hematocrit and hemoglobin remained within acceptable limits without further protein replacement therapy. Soft white healing by primary intention resulted.

In the light of subsequent experience the wound in this case could also have been closed several days earlier. Even on the eighth day it was possible to close the fascia as a distinct layer.

CASE 6 (Fig. 4) A 51 year old male had drainage of an intra-abdominal abscess secondary to a ruptured appendix on July 28, 1947. Because of small bowel obstruction caused by the abscess and unrelieved by a Miller Abbott tube the surgeon did a double pursestring catheter ileostomy and brought the catheter out through the wound. Eight days post-operatively the wound was opened because of undermining infection and necrosis from the discharge of bowel contents through the everted ileostomy stoma which presented itself in the wound just beneath the skin, the catheter having been extruded. A culture yielded *Escherichia coli*, *Bacillus subtilis* and diph-

TABLE I—EARLY CLOSURE AFTER WIDE OPEN DRAINAGE IN MASSIVE WOUND INFECTIONS

Case No.	Diagnosis	Type of wound infected	Source of contamination	Opening to closure	Healing
	Cancer of rectum	Abdominal (Miles operation)	Colostomy in wound	3 days*	Primary
	Cancer of rectum	Abdominal (abdominoperineal resection)	Adjacent colostomy	8 days†	Primary
3	Carcinomatous intra-abdominal	Abdominal	Colostomy in wound	3 days	Healing expired 9th day
4	Cancer of colon	Abdominal	Adjacent colostomy	1 day†	Primary
5	Cancer of rectum (dehiscence)	Abdominal	Adjacent colostomy	**	Primary
6	Abscess, intraperitoneal (ruptured appendix)	Abdominal	Trostomy in wound	4 days†	Primary
7	Cancer of cecum	Abdominal (carcinoma exteriorized)	Colostomy in wound	days	Primary
8	Recurrent cancer of colon (intestinal obstruction)	Abdominal	Adjacent colostomy	4 days†	Failure
9	Cancer of transverse colon	Abdominal	Intra-abdominal incision—fecal fistula	**	Unsatisfactory
	Intestinal obstruction (small bowel)	Abdominal	At dehiscence	days	Primary
	Cancer of cecum	Abdominal	At operation	3 days‡	Satisfactory
	Cancer of cecum	Abdominal	At operation	7 days‡	Satisfactory
12	Cutaneous sinus (inguinal)	Inguinal herniorrhaphy	At operation	3 days	Primary
4	Ruptured appendix	Abdominal	At operation	days†	Primary
5	Breast abscesses (multiple)	Inguinal herniorrhaphy	At operation	**	Primary
6	Compound fracture both bones of leg	Leg (partial closure)	At accident	7 days	Satisfactory
7	Diabetic necrosis	Perineum	Asar	0 days	Primary

*Treated with 0.5% urethane solution

†Layer closures

**Closed at time of drainage and debridement

‡Treated with 0.5% urethane 1% sulfanilamide mixture

(Table I) All were surgically closed within less than 14 days after open drainage except 1, an abscess of the perineum which was opened and closed in two stages in 19 days.

There were 15 successful closures and 2 failures. Of the successful cases 11 wounds healed by primary intention with soft white healing. In Case 11 healing was satisfactory but with a small area of granulation tissue at one end of the wound. In Cases 12, 15 and 16 there was slight induration and redness around the wound for several days. For this reason they were not classified as healing by primary intention although the clinical end results were as good as those with true primary healing.

Layer closure was done in 5 instances (Cases 2, 4, 6, 8 and 14).

Of the 13 patients with abdominal wounds 8 had fecal discharge into the wound.

The average elapsed time from opening to closure in all wounds was 7.41 days.

A brief résumé of the 2 failures in our series follows.

CASE 9. A 54 year old single female factory worker had a Mikulicz resection of a carcinoma of the transverse colon and a resection of 25 square inches of her right lateral abdominal wall to which the carcinoma was adherent, on May 25, 1946. She made an uneventful convalescence gained weight and returned to work. On follow-up examination a small nodule was palpable within the colostomy against the lateral abdominal wall. It remained stationary in size for 5 months and it was thought to be scar tissue at the site of plastic closure of the abdominal wall defect. On September 5, 1946 the colostomy was closed at which time the nodule was biopsied and proved to be adenocarcinoma grade II. A fecal fistula developed, persisted for several months, and finally healed. A progressively enlarging mass appeared beneath the incision. In spite of this she remained vigorous and did not lose weight. On June 4, 1947 she presented herself with small bowel obstruction of several days duration. After 10 days of Miller Abbott tube decompression an exploratory laparotomy was done on June 14, 1947. A matted mass of intestines and carcinoma occupied the right half of the abdominal

wound infection and remained firm throughout the course of treatment.

Once having accepted and practiced the principle of wide open drainage for postoperative infections one is confronted with the problem of treatment and closure of an open wound. The necessity for a protective dressing in the face of fecal contamination is obvious and the presence of devitalized tissue or invasive infection calls for the use of moist dressings. The utilization of a solution which contains antibacterial agents seems rational provided these agents are not detrimental to wound healing and are capable of inhibiting the bacterial flora and improving the gross appearance of the wound. If these principles prove successful in the management of wounds bathed in feces they should be even more efficacious in wounds not so complicated. Such has been our experience in the few preliminary cases reported here. The advantage of urethane-penicillin mixture over saline was exemplified in Case 1 in which it seemed obvious that the mixture was helping to hold *Pseudomonas pyocyaneus* in check. Once a postoperative wound infection has been converted to a clean wound it can be treated as any open wound and surgically closed.

The true age of most of these wounds dates from the time of the original operation and not from the time of drainage and débridement. Thus they are not strictly comparable to the war wounds on which the concept of an optimal closure period extending from the fourth to the tenth day is based. From 5 to 7 days has usually elapsed before the infection is discovered and this fact probably explains why layer closure cannot be more often accomplished.

The early closure of infected wounds unaccompanied by a source of recontamination has been accomplished without difficulty. At first we were hesitant about closing wounds with feces draining into them but now believe that many of them can be closed on the fourth to sixth day if properly treated. Meticulous attention to detail and faithful nursing care are essential. Although the use of urethane penicillin mixtures has seemed to be a useful aid in the conversion and closure of these wounds it is not to be thought of as the pre-dominant factor for the application of sound

surgical principles. The correction of anemia and the restoration of tissue proteins are of paramount importance. It is difficult to assess the value of continued systemic antibiotic and chemotherapy when the infection being treated develops despite their prophylactic use.

Case 9 classed as a failure is included even though the problem was not that of treatment of an established wound infection. An attempt was made to use urethane-penicillin mixture as a prophylactic in a contaminated wound. The wound had partly healed when the fecal fistula developed and contaminated it from within a situation with which no antibacterial measures can be expected to cope. The other failure was in a debilitated, depleted 78 year old lady with peritoneal carcinomatosis in whom the usual protein restorative measures were ineffective. It was probably an error in judgment to attempt closure of her wound. This is a true failure attributable to irreversible fault in the processes which influence wound healing.

CONCLUSIONS

A method for the treatment of postoperative wound infections is outlined and the need for the use of wide open drainage and careful débridement is emphasized.

A combination of early wide open drainage proper application of the principles of reparative surgery and topical antibacterial therapy allows conversion of postoperative wound infections with a constant source of fecal contamination into 'clean' wounds which may be surgically closed within a short period of time thus averting many of the complications of wound infections.

Layer suturing may be accomplished early in the optimal period for wound closure.

Urethane-penicillin mixture by virtue of its action upon both gram negative and gram positive bacteria appears to be a useful adjunct to reparative surgery.

Seventeen patients with postoperative infected wounds 8 of whom had a colostomy in or adjacent to the wound have been treated and the wounds surgically closed within an average of 7.41 days after open drainage. There were 2 failures. Primary healing occurred in 11 cases.

A LARGE PULSION ESOPHAGEAL DIVERTICULUM WITH COMPLICATIONS

FRANK H LAHEY MD., F.A.C.S. Boston, Massachusetts

THE report of a single case of large esophageal diverticulum of the pulsion type particularly from a clinic where 270 patients with such diverticula have come to operation could well seem peculiar were it not for the fact that the complications in this case were of such variety and nature that an opportunity presented itself to demonstrate and discuss their management.

REPORT OF A CASE

A man aged 67 years, complained of difficulty in swallowing which had been present for 40 years. When he was about 26 years of age this difficulty in swallowing began and has gradually become worse until recently he has been able to swallow very little solid food. As he ate a swelling would appear in the anterior left portion of his neck as a result of the accumulation of food within the large diverticular sac. This food caused the patient discomfort and by his exerting external pressure over the mass the food was regurgitated. Patient originally weighed 160 pounds at the time of admission he weighed 127 pounds having lost 30 pounds during the last 2 or 3 years (Figs 1 and 2).

The patient was seen by the members of the medical department of the clinic who ascertained that 6 weeks before his admission a right sided pneumonia had developed which was treated successfully with penicillin. He has had a chronic mild cough since that time but other than arteriosclerosis cardiac hypertrophy and auricular fibrillation nothing abnormal was noted in his physical findings. Operation for removal of the diverticulum was advised.

MECHANISM OF OBSTRUCTION

In previous papers and discussions on this subject¹ attention has been called to the fact that obstructive symptoms in patients with pulsion esophageal diverticula occur only when the sacs have become large enough to pull upon the opening into the esophagus beyond the neck of the sac. Thus the esophagus instead of being in the transverse position so that food passes directly into it on swallowing is converted into a lateral position by the

downward traction of the food filled sac and the opening into the diverticulum becomes transverse so that swallowed food or introduced instruments (esophagoscope or bougie) pass directly into the sac and not directly into the esophagus itself.

This is well illustrated in Figure 1 of the large barium filled sac of the diverticulum. Note in the illustration that the course of descent of the swallowed barium is directly into the sac while the barium spilling over the edge of the transverse opening into the diverticular sac passes into the now lateral opening into the esophagus and is shown as a thin tract of barium. This thin tract is the obstruction and the reason that patients who have large diverticula as in this case do not obtain adequate nourishment and for this reason lose weight.

Two hundred and seventy patients with esophageal diverticula were operated upon at this clinic in 5 of the patients an esophagoscope or bougie had been pushed through the end of the sac at another clinic resulting in mediastinitis. All of these patients have survived 1 required a posterior mediastinotomy, 1 required multiple incisions in the neck and a gastrostomy and all had a very narrow escape from a fatality. In presenting an explanation of this type of obstruction I have always called attention to the fact that since the opening into the true esophagus is at the side of the sac, it is impossible to manipulate an esophagoscope into the true esophagus as it will always go directly into the sac. I wish again to warn those who are inexperienced with esophageal diverticula and unaware of this fact that in those cases in which the opening into the esophagus is lateral the introduction of the esophagoscope or an attempt to pass bougies is extremely dangerous and persistence in pressure after the instrument or the bougie has entered the sac will result in perforation at its end.

Fig. 1. Roentgenogram showing the sac of the diverticulum. One can perceive in diverticulum of this depth that the parietal pleura becomes adherent to and encloses the sac and that as occurred in this case there is the danger of tearing it as the sac is separated from it.

Fig. 2. Not the diagnostic point that is true of all lateral view of esophageal diverticula, that the stream of barium passing to the esophagus comes from behind and from the upper part of the sac and not from the most dependent portion of the sac.

RUPTURE OF THE PLEURA IN DELIVERING THE SAC FROM THE CHEST

It must be remembered that when the sac of the diverticulum is as large as it was in the present case (Figs. 1 and 2) the lower portion of the sac will be enveloped by and adherent to the pleura; that the pleura is a delicate structure and that as the sac is pulled out of the chest and the pleura freed from it there will be danger of tearing the adherent pleura; an unwittingly occurred in this case with such immediate effect upon the mechanism of breathing that cessation occurred.

Since intratracheal cyclopropane anesthesia was used in these patients no serious difficulty was encountered; the anesthetists were able to continue respiration mechanically by means of the breathing bag. It was not until the sac was completely delivered that the wide rupture in the apex of the pleura with its partly collapsed lung beneath it could be demonstrated as the cause of the respiratory difficulty. The introduction of a large wet pack into the

opening of the pleura to plug it temporarily permitted the restoration of respiration and closure of the pleural rent was delayed until the diverticular sac was completely dissected at its neck and ready for implantation in the wound at the completion of the first stage of the operation.

Before the wound in the neck was closed the wet pack was withdrawn from the opening in the pleura; the anesthetist expanded the lung by positive pressure and the torn edges of the ruptured pleura were without difficulty approximated by interrupted sutures of fine silk. A cigarette drain with a large strip of gauze projecting from its end was placed in the mediastinum; the sac was implanted in the wound and the skin was closed about it as is the custom in the two stage operation. A No. 24 F catheter was then introduced into the pleural cavity between the fourth and fifth ribs through a trocar; the lung was expanded by suction upon this catheter and the end of the rubber tubing connected with it was carried

into a bottle of water below the level of the patient (Fig 3). This catheter was removed in 48 hours; there was no further collapse of the lung. The drain into the mediastinum was removed on the sixth day with no further pulmonary collapse. There were no further complications as the result of the rupture and suture of the pleura.

Whatever our position may be regarding one or two stage operations in pulsion esophageal diverticula, and my favoring of the two stage operation is too well known to require repetition; its safety and advantages in a case such as this must be admitted. It is my opinion that the dangers of mediastinitis in the one stage operation are greatly increased in patients with large diverticular sacs since in these large sacs the opening into the esophagus where the sac joins that structure is large and its accurate suture and inversion difficult and uncertain. It is also made more dangerous by the very large cavity which remains in the mediastinum after removal of such large sacs from their position in the chest. It must be remembered that the neck of the diverticulum usually enters the esophagus in the midline in back—at the pharyngo-esophageal junction—that at this level where the esophagus joins the pharynx, the esophagus cannot be freely mobilized or rotated, and that adequate exposure and accurate suture of the esophagus after the sac is cut away is often extremely difficult and frequently far from accurate, thus exposing these patients to the risks of leakage and contamination of so deep an intrathoracic cavity. This is not to be feared when the sac is not cut away and its neck sutured into the wound. By this plan the mediastinal cavity and fascia planes become walled off by protective granulations and adhesions and should leakages occur at the second stage amputation and closure of the sac they will not result in serious complications.

OVERDISTENTION OF THE IMPLANTED SAC BY SWALLOWED AIR

Ballooning of the sac (Fig 4) is caused by the swallowing of air. We have seen this complication in several patients with large sacs after implantation in the neck and after the wound has been sutured about it. Continued

Fig 3 This roentgenogram shows the catheter which was introduced into the right chest between the fourth and fifth ribs to re-expand the lungs after the pleura, torn at the time of operation, had been sutured. On the left side note the outline of the sac, as indicated by arrows, shown in a later illustration distended by air when it was implanted on the neck.

accumulation of air within the sac increases its volume and if distention is continued gangrene of the sac will follow. As the result of the traction of the neck of the distended sac upon the esophagus itself, lateral traction exerted upon the esophagus will cause complete obstruction and interference with the intake of an adequate amount of fluid and nourishment.

Distention of the sac is immediately relieved by the introduction of a decompressing catheter by means of a pursestring suture into the sac (Fig 5). At the end of 3 or 4 days when the wound has healed about the neck of the sac, the excess sac may be cut away (Fig 6).

THE PROBLEM OF FEEDING THE PATIENT BETWEEN STAGES

In the present case because the diverticular sac was so large together with the fact that the pleura had been opened and sutured, and also because following the delivery of the sac from the mediastinum, there remained a large mediastinal cavity the problem of feeding the

Fig. 1. Roentgenogram showing the size of the diverticulum. One can appreciate in the diverticulum of this depth that the pleural pleura becomes adherent to and envelops the sac and that as occurred in this case, there is the danger of tearing it as the sac is separated from it.

Fig. 2. Note the diagnostic point that is true of all lateral views of esophageal diverticula, that the stream of barium passing into the esophagus comes from behind and from the upper part of the sac and not from the most dependent portion of the sac.

RUPTURE OF THE PLEURA IN DELIVERING THE SAC FROM THE CHEST

Fig. 6.

Fig. 7.

Fig. 4. Photograph of patient showing the distention of the sac which was swallowed by the patient. This complication occurred between the first and second stages of the operation and made necessary decompression, as shown in Figure 5.

Fig. 5. The same sac as shown in Figure 4, after decompression by the introduction of a catheter.

Fig. 6. This view was taken after the major portion of

the sac had been amputated at the end of the fourth day thus permitting the manual introduction of a catheter through the neck of the sac into the esophagus and then on into the stomach. The patient was fed through this catheter until he was ready for the second stage removal of the sac.

Fig. 7. The wound is completely healed after the sac has been completely cut away and sutured at its neck.

patient between the first and second stages of the operation became a difficult one consequent distortion of the course of the true esophagus made it impossible for the patient to swallow.

Fig. 8. A roentgenogram of the esophagus showing the final stage with the sac completely removed, the wound closed, and no defect remaining.

Since there remained a large mediastinal cavity at the bottom of which was a large recently sutured rent in the pleura it seemed wise not to do at the usual time 7 days after the first operation the second stage of operation namely the reopening of the wound in the neck the severing of the sac at its neck and the suturing of the remaining opening in the esophagus but to wait 2 weeks until the rent in the pleura was well healed and the large mediastinal cavity largely obliterated.

The feeding problem was easily handled in this case by cutting away the excess walls of the sac at the end of the fourth day when the walls of the implanted sac were firmly adherent to the wound in which the sac had been implanted and when the overdilated sac had been decompressed by the introduction of a catheter. Through this large aperture opening directly into the esophagus a Levine tube could easily be guided by the finger directly into the stomach. Through this tube the patient was fed without difficulty until ready for the second stage of the operation the removal of the remainder of the sac and the suture of the defect made in the esophagus by the cutting away of the neck of the sac (Fig. 6). With closure of the esophagus at the second stage operation and with wide exposure by reopening the original longitudinal incision in the neck by complete separation of the remaining implanted neck of the sac from the

edges of the wound together with complete mobilization of the esophagus itself up to the point where the sac joined the esophagus, an accurate inversion suture in two rows of the open edges of the esophagus could be made. As is our custom a tube was passed through the nose into the stomach and the patient was fed for a week through this, at the end of which time the tube was removed. There was no leakage the reopened wound had healed without difficulty (Fig 7) and the patient was swallowing well. The roentgenogram (Fig 8) shows that there is no remaining sac or obstruction.

It can be said of course that had this operation been done in one stage with immediate amputation of the sac and immediate closure of the opening into the esophagus made by the removal of the sac some of the complications mentioned here would not have occurred such as overdistention of the sac with air the need to decompress it, and the need to feed the patient by tube for the 15 day period between the first and second stages of the operation. Whatever one may think of one or two stage operations in patients with esophageal diverticula if one has done many of them he must admit that in a patient in whom the pleura has

been opened and sutured at the bottom of a cavity of such dimensions as present in this patient, the likelihood of a leak at the suture line in the esophagus would have been greatly multiplied. Whatever may be said about the relationship in this case of the complications to the two stage procedure, the two stage plan did make possible the successful safe handling of the complications without leakage and mediastinal infection.

SUMMARY

A case is presented of a large esophageal diverticulum which had a large intrathoracic sac.

The following complications occurring during the operation and their management are discussed: rupture of the pleura during the operation and its repair; overdistention of the implanted sac requiring decompression; partial amputation of the sac and introduction of a tube through the neck into the stomach; delay in second stage to permit healing of the pleura and the obliteration of the mediastinal cavity.

Roentgenograms and photographs are shown to illustrate some of the complications and the method of management.

CHEMOTHERAPY IN PERITONITIS DUE TO PERFORATION OF AN ABDOMINAL VISCUS

E. M. COLVIN M.D., and FURMAN T. WALLACE, M.D., Spartanburg, South Carolina

THE use of the sulfonamides penicillin and streptomycin has done much to improve the results obtainable in the treatment of peritonitis secondary to contamination from the alimentary tract. Peritonitis of this type usually results from a perforation of some portion of the gastrointestinal tract from trauma from infection or from contamination during a surgical procedure. The infection is usually mixed but the predominant causative organism is most often the colon bacillus.

The sulfonamides are not considered effective against the colon bacillus but are of considerable value in combatting numerous other organisms in the mixed infection group. However, sulfasuxidine and other sulfonamides are effective in reducing the *Escherichia coli* count of the stool when given orally and it would seem that they would also be effective against the same organism in peritonitis.

Penicillin in its usual dosage is not effective against this type of peritonitis. However, in massive doses it adequately controls these mixed infections. Just how this is accomplished is still not definitely determined but the conclusions reached by Crile (4, 5) seem very logical. *Bacillus coli* and other penicillin resistant organisms produce penicillinase which is an enzyme-like substance capable of inactivating penicillin. Usual doses of penicillin are not capable of overcoming this penicillinase effect of the *Bacillus coli* but when large doses are given this effect is overcome. Then penicillin becomes effective against the virulent gram-positive cocci although it theoretically does not inhibit the colon bacillus. This organism and most of the penicillin resistant organisms are not virulent or invasive and can be combatted effectively by the high natural resistance of the peritoneum when the virulent gram positive cocci are controlled.

From the Department of Surgery, Spartanburg General Hospital.

Therefore it is important that adequate amounts of penicillin be given early and continued for a sufficient length of time.

Streptomycin acts primarily on the gram negative organisms and is effective in adequate dosage in peritonitis due to *Bacillus coli* but is not as effective as penicillin on other members of the mixed infection group. A disadvantage to streptomycin is that the toxic reactions are relatively frequent and permanent whereas those to penicillin are minor and temporary.

The cases of this type of peritonitis during a 12 month period are presented with the amount of drug or drugs used and several important factors in treatment are discussed. We will also present what we consider an adequate chemotherapeutic regimen in peritonitis due to contamination from the gastrointestinal tract.

DISCUSSION

In reviewing the cases presented (Table I) several interesting conclusions can be reached regarding the value of chemotherapy in this type of peritonitis.

In cases in which the peritonitis was early and in which no purulent exudate was present in the peritoneal cavity the dosage of penicillin needed was much smaller than in more advanced cases. This was evidenced in Cases 1, 2, 10, 13, and 15. It is probable however that even in these cases the initial dosage should have been greater because it is very important to obtain and maintain a high concentration of the drug at the onset.

In several of the cases 200,000 units of penicillin were left in the peritoneal cavity. We feel that this is a valuable adjunct to parenteral therapy for it provides a high concentration at the site of contamination. Sulfathiazole crystals were left in the peritoneal cavity in several cases and we think that it was of some value in combatting the mixed infections. Never more than 5 grams were used.

and that was distributed carefully so that there was no lumping or caking of the crystals which would provide a large foreign body in the peritoneal cavity

Sulfonamides were never used alone but always in combination with penicillin or streptomycin or both. In some of our cases they were not used at all, and the results were apparently not altered by the absence of the sulfonamides. Nevertheless, in cases of mixed infection, we do not feel that it can be omitted

In several of our cases, streptomycin was used in moderate dosage although it may have been unnecessary in some instances. It was used initially in 3 cases of fulminating peritonitis (Cases 5 and 19) and was started on the second or third postoperative day in 4 cases (Cases 6 11 12 and 18) when there was still a sustained temperature elevation. The response in all cases was satisfactory.

One fact that needs emphasis is that prompt surgical intervention is necessary to eliminate the source of contamination to the peritoneal cavity. The exception to this is of course an instance in which the peritonitis appears to be well localized. Even in such a case surgical intervention may be necessary to deflate the bowel if there is an obstruction (Cases 6 and 16) or to provide adequate surgical drainage. In some instances of ruptured appendices where the peritonitis was well localized with definite abscess formation, it was not feasible to remove the appendix at the time of incision and drainage. In these cases the appendix was removed later when all infection had subsided. Occasionally the appendix will be free in the abscess cavity and can be removed with no danger of spreading the infection.

An interesting fact was illustrated in Case 11 in which the penicillin dosage was decreased too soon, and there was an increase in the temperature elevation and also evidence of increased peritoneal irritation. The penicillin dosage was increased to the original amount and streptomycin was begun. The end result was satisfactory, but several days were added to the hospital stay.

Our conclusions as to the dosage of these chemotherapeutic agents are as follows:

1. In early peritonitis with little contamination of the peritoneal cavity 200,000 units of

penicillin are left in the peritoneal cavity. Then 100,000 units intramuscularly are given preoperatively and every 2 hours postoperatively for 10 to 12 doses. If by that time the temperature and the peritoneal signs are normal, the dosage is reduced to 100,000 units every 3 hours for 8 doses and then 50,000 units every 3 hours for another 48 hours.

The sulfonamides are not used ordinarily in this type of case and streptomycin is reserved for use if it appears that the penicillin is not accomplishing satisfactory results. This can usually be determined within 24 to 36 hours.

2. In cases of localized peritonitis with abscess formation both penicillin in dosage of 50,000 to 100,000 units intramuscularly every 3 hours and sulfonamides in usual dosage either by mouth or intravenously are given both preoperatively and postoperatively. If contamination of the general peritoneal cavity is known or suspected after incision and drainage of the abscess, the penicillin dosage should be 100,000 units every 2 hours for as long as is necessary.

Penicillin and sulfonamides are both of value locally in the abscess cavity—200,000 units of the former and not over 5 grams of the crystalline form of the latter being the recommended dosage. In certain instances, it may be feasible to irrigate the abscess cavity with a solution of penicillin.

Streptomycin is reserved in these cases as in the first group for use if the penicillin and the sulfonamides seem inadequate.

3. In cases of advanced peritonitis where there is gross contamination of the peritoneal cavity with a purulent exudate present, we feel that all three drugs should be used as long as is necessary in adequate dosage as follows:
 - a. Penicillin 100,000 units intramuscularly every 2 hours with 200,000 units left in the peritoneal cavity at operation.

- b. Streptomycin 0.1 gram to 0.3 gram every 3 hours in the usual case or as much as 0.5 gram every 3 or 4 hours in more severe cases.

- c. Sulfonamides in usual dosage either by mouth or intravenously—usual dosage being approximately 1 to 1.5 grams every 4 hours. The crystalline form of the sulfonamides not exceeding 5 grams in amount may be used in the peritoneal cavity.

TABLE I.—SUMMARY OF CASES

File No. Case	Age Race Sex	Diagnosis	Operations	Hospital course	Chemotherapy—results
1700	4 White Male	Ruptured duodenal ulcer. Generalized peritonitis, early	Repair of ruptured duodenal ulcer	Satisfactory. No complications. Discharged in good condition on the 5th postoperative day	Penicillin, 11,000 units I.M. every 3 hours for 3 days. Intravenous sodium sulfadiazine 2 gm. daily for 3 days. Satisfactory result.
16,701	8 White Female	Ruptured appendix. Early peritonitis, generalized	Appendectomy. Free-out drainage	Temperature 100° to 101° F. for 3 days. Discharged in good condition on the 6th postoperative day	Penicillin, 11,000 units I.M. every 3 hours for 3 days. Sodium sulfadiazine 2 gm. daily for 3 days. Intravenous placebo in N/S—satisfactory result.
108,805	46 White Female	Ruptured appendix. Localized peritonitis and abscess formation	Ligation and drainage of appendiceal abscess. Appendectomy	Admitted with diagnosis of pelvic abscess of appendiceal origin. Treated conservatively with chemotherapy for one week—abscess drained and drainage of appendiceal abscess with removal of abscessed and appendicitis. Discharged in good condition on 10th postoperative day	Penicillin, 10,000 units every 3 hours for 5 days. Sulfadiazine in usual dosage. Satisfactory result.
104,49	4 White Male	Ruptured appendix. Generalized peritonitis (purulent)	Appendectomy with drainage	Stoic course with temperature 101° to 102° for 8 days. Free abdominal status. Moderate respiratory distress. Discharged in good condition on the 10th postoperative day	Penicillin, 11,000 units I.M. every 3 hours for 3 days—then 10,000 units I.M. every 3 hours for 3 days. Sodium sulfadiazine intravenously in usual dosage for 10th. Satisfactory result.
14,177	1 White Female	Generalized peritonitis with multiple abscess formation. Focal abscess. Subcapsular abscess (drained previously). All of 4 weeks' duration on admission to this hospital and postoperative is appendicitis and peritonitis (with appendectomy)	Appendectomy (done elsewhere prior to admission to our service). Ligation and drainage of subcapsular abscess (done elsewhere prior to admission to our service). Exploration for possible abscess in pelvic region	Very poor condition on admission here. Temperature elevation 101° to 102° but gradually dropped to normal on the 4th day. Hemorrhagic transudate of plasma and whole blood present. General condition as appeared very satisfactory when she developed a fulminating hepatitis. With intensive penicillin which progressed rapidly. Patient expired 11th at 48 hours on the 5th hospital day	Penicillin, 100,000 units every 6 hours for about 6 weeks. Streptomycin 1 gm. every 6 hours for about 1 month. Sulfadiazine in usual dosage for 3 to 4 weeks. Patient expired on 5th hospital day. Autopsy revealed cause of death to be fulminating hepatitis. Peritonitis had completely cleared and only transient peritoneal adhesions remained.
1,067	6 White Female	Ruptured diverticulum of sigmoid with complete intestinal obstruction and localized peritonitis	Cececstomy. Segmentectomy	Was stuporous prior to operation and in poor condition, however responded reasonably after drainage of distention. Temperature spiked to 104° for 3 days and gradually returned to normal by the 4th postoperative day	Penicillin, 100,000 units every 6 hours for 6 days; then 100,000 units every 6 hours for 20 days. Streptomycin 2 gm. every 6 hours for 2 days. Sulfadiazine in usual dosage. Patient responded. It was discharged for 3 months and returned for closure of the cecostomy with satisfactory results.
10,630	67 White Male	Perforated duodenal ulcer. Early peritonitis	Repair of perforated duodenal ulcer	Postoperative course was quite satisfactory until 4th postoperative day when he developed mild respiratory distress that responded to penicillin by solution. Temperature on 5th day 100° and was normal on the 6th day	Penicillin, 100,000 units every 6 hours for 6 days—and penicillin via nebulizer for 4th. Patient responded readily to postoperative and was discharged in good condition on the 15th postoperative day
9,906	6 White Male	Appendiceal abscess	Ligation and drainage of appendiceal abscess	Postoperative course was unremarkable. Considerable drainage for 2 weeks. Temperature was 101° to 102° for 9 days and then gradually became normal on the 16th postoperative day	Penicillin, 30,000 units every 3 hours for 7 days. Sulfadiazine in usual dosage. Patient responded readily and was discharged on the 16th postoperative day. Returned 1 month later and an appendectomy was done
141,180	3 White Male	Ruptured appendix. Generalized peritonitis. Subphrenic abscess	Appendectomy with drainage. Ligation and drainage of subphrenic abscess. Exploration of drainage tract of subphrenic abscess	Patient was sustained temperature elevation of 101° to 102° for 4 days which gradually became normal on the 17th day. Subphrenic abscess was drained on the 17th and 18th days	Penicillin, 100,000 units intramuscularly every 6 hours for 1 week. Penicillin to irrigate subphrenic abscess cavity. Sulfadiazine in usual dosage. Discharged in good condition on the 18th postoperative day
73	46 White Female	Ruptured appendix. Generalized peritonitis, early	Appendectomy. Free-out drainage	Sustained temperature elevation to 102° F. for 3 days. Normal on 6th postoperative day	Penicillin, 60,000 units every 6 hours for 6 days; then 30,000 units every 3 hours for 7 days. Sulfadiazine in usual dosage for 6 days. Discharged in good condition on the 13th postoperative day

TABLE I.—SUMMARY OF CASES—Continued

COLVET

TABLE I.—SUMMARY OF CASES

File No. Case	Age Race Sex	Diagnosis	Operations	Hospital course		Chemotherapy—results
				Temperature of rectum gradually dropped to normal on the 2nd postoperative day. Rose again on the 5th day and remained between 100° and 101° for 5 days; then became normal and remained so		Penicillin, 100,000 units every 4 hours for 4 days, then 50,000 units every 4 hours. Sulfadiazine in usual dosage. Streptomycin 1 gm. every 3 hours for 7 days—started on 6th postoperative day at height of second temperature rise. Discharged in good condition on 8th postoperative day
5,468 11	White Male	Ruptured appendix. Generalized peritonitis, (parent)	Appendectomy with drainage	Temperature elevation 101° to 102° for 3 days. Normal on 3rd postoperative day. Discharged in good condition on the 6th postoperative day		Penicillin, 100,000 units every 4 hours for 4 days. Sulfadiazine in usual dosage. Streptomycin 1 gm. every 3 hours for 3 days. Satisfactory result
145,138	40 White Male	Ruptured appendix. Early peritonitis, localized	Appendectomy without drainage	Smooth course—no temperature elevation. Discharged in good condition on 6th postoperative day		Penicillin, 50,000 units every 4 hours for 4 days. Satisfactory result
145,768 13	20 White Male	Perforated duodenal ulcer. Early peritonitis, generalized	Repair of perforated duodenal ulcer	Temperature elevation 100° to 101° for 3 days. Normal on 6th day. Discharged in good condition on the 6th postoperative day—to return in 6 weeks for an appendectomy		Penicillin, 100,000 units left in peritoneal cavity 1 time of operation. Penicillin, 100,000 units I.M. every 4 hours for 10 days, then 50,000 units every 4 hours for 4 days. Sulfadiazine in usual dosage. Satisfactory result
145,684 4	24 Colored Male	Ruptured appendix with localized abscess. Peritonitis, generalized	Incision and drainage of appendiceal abscess	Temperature elevation 101° to 102° for 4 days. Due in part to flare-up of chronic bronchitis which responded readily to penicillin via nebulizer. Discharged in good condition on 10th postoperative day		Penicillin, 100,000 units left in peritoneal cavity 50,000 units penicillin I.M. every 3 hours Satisfactory result
77,18 5	White Male	Ruptured duodenal ulcer. Early peritonitis, generalized	Repair of ruptured duodenal ulcer	Gastric tube administration with marked duodenal distention. Sustained temperature of 101° to 102°. Improved rapidly after distention of bowel and chemotherapy begun. Discharged in good condition on 3rd hospital day		Penicillin, 50,000 units every 4 hours for 3 days. Local irrigation of peritoneum with penicillin solution. Sulfadiazine in usual dosage when oral medications could be taken. Satisfactory result
64,057 6	44 White Male	Intestinal obstruction (colon) due to ruptured diverticulum. Localized peritonitis. Diabetes mellitus	Appendectomy	Extremely ill—shock. Peritoneal cavity grossly contaminated with fecal material. Sustained temperature elevation of 101° to 102° for 4 days. Discharged in good condition on the 4th postoperative day		Penicillin 100,000 units left in peritoneal cavity 50,000 units every 3 hours I.M. for 4 days, then 100,000 units every 4 hours for 7 days. Sulfadiazine crystals 5 gm. in peritoneal cavity Sulfadiazine in usual dosage. Patient was discharged in good condition and returned 3 months later for closure of colostomy
6,051 7	49 White Female	Perforation of rectum. Generalized peritonitis	Repair of perforation of rectum. Colostomy	Temperature 100° to 101° for 4 days, then normal. Discharged in good condition on the 11th postoperative day		Penicillin, 100,000 units every 4 hours for 4 days. Streptomycin 0.5 gm. every 3 hours for 4 days. 2-5 gm. sulfadiazine crystals left in peritoneal cavity Sulfadiazine in usual dosage. Satisfactory result
97,158 8	14 White Female	Ruptured appendix. Early peritonitis, generalized	Appendectomy without drainage	Admitted to hospital in state of shock—abdomen markedly distended—tender right. Temperature 102° at admission. Temperature rose to 103° and became normal day after the 6th postoperative day. Discharged in good condition on the 11th postoperative day		Penicillin 100,000 units in I.V. glucose in normal saline prior to operation. Streptomycin 1 gm. every 3 hours I.M. for 7 days. Sodium sulfadiazine 5 gm. in I.V. glucose I.D. for 6 days. Satisfactory result
45,450 9	Colored Male	Ruptured appendix, walled off. Paralytic ileus due to infection	Appendectomy without drainage	Admitted to hospital with marked distention of abdomen, tenderness and rigidity. General condition poor. Temperature 102° at admission. Temperature 101° and 102° for 3 days; then became normal. Has had weekly therapeutic drainage. General condition good		Penicillin 100,000 units in peritoneal cavity 1 operation. Penicillin 100,000 units every 4 hours I.M. for 10 days, then 50,000 units every 3 hours for 7 days. Streptomycin 0.5 gm. every 3 hours for 4 days. Sodium sulfadiazine 5 gm. in peritoneal cavity 1 operation. Result satisfactory. Patient will have appendectomy at later date
45,664 10	68 Colored Female	Ruptured appendix with abscess. Generalized peritonitis, parent, late	Incision and drainage of appendiceal abscess and generally contaminated peritoneal cavity	Admitted to hospital in state of shock—abdomen markedly distended—tender right. Temperature 102° at admission. Temperature rose to 103° and became normal day after the 6th postoperative day. Discharged in good condition on the 11th postoperative day		Penicillin 100,000 units in I.V. glucose in normal saline prior to operation. Streptomycin 1 gm. every 3 hours I.M. for 7 days. Sodium sulfadiazine 5 gm. in I.V. glucose I.D. for 6 days. Satisfactory result

acute appendicitis, perforated, adequately sealed off at operation by portion of the omentum was not included since the peritoneal cavity. Prophylactic chemotherapy was used in some

NOTE.—Several cases of acute appendicitis, perforated, adequately sealed off at operation by portion of the omentum were not included since the appendix and the involved omentum were removed without contaminating the peritoneal cavity. Prophylactic chemotherapy was used in some of these cases.

SUMMARY

- 1 The effectiveness of chemotherapy in peritonitis secondary to contamination from the alimentary tract has been discussed.
- 2 A chemotherapeutic regimen for this type of peritonitis has been outlined.

THE TREATMENT OF ACUTE RENAL INSUFFICIENCY

E. E. MUIRHEAD M D and J M HILL, M D., Dallas, Texas

A SERIES of different conditions are associated with acute bilateral renal damage and acute renal insufficiency. The syndrome resulting from this type of renal lesion has been designated by different terms such as 'renal anoxia syndrome' (18), 'lower nephron nephrosis' (14) and 'hemoglobinuric nephrosis' (26). It has been frequently stressed in various publications that once renal insufficiency is definite the mortality rate in this group of cases is very high. Thus, Lucké placed the mortality rate near 90 per cent and Mallory stated that with persistent oliguria and hypertension the chance of survival was not much more than 20 per cent.

From a clinical viewpoint it appears that the most common condition associated with this lesion is that of prolonged hypotension particularly that due to oligemia. In a general hospital one may encounter such cases following copious hemorrhages as in traumatic operative and obstetrical cases. It was the frequency of circulatory failure in the various conditions associated with acute renal insufficiency that led Macgrath and coworkers (17) to the conclusion that renal anoxia constituted the main cause of the renal lesion. Other conditions associated with similar renal changes include incompatible (hemolytic) blood transfusions (27), the crush syndrome (2), blackwater fever (5), burns (8), severe alkalosis (21, 23), carbon tetrachloride poisoning (29), heat stroke (19), sulfonamide intoxication (7), severe pyrogenic reaction (1) and transurethral prostatectomy with water hemolysis (4, 22).

In reported cases there has been a frequent attempt to stimulate the kidneys to produce urine during the oliguric period. A common measure used for this purpose has been a prominent fluid intake with or without added salt. In many cases generalized edema and acidosis have been outstanding features of the syndrome, pulmonary edema being striking

Most patients have expired within 8 days (14). Morphologically it has been noted that regeneration of renal tubules is well advanced by the eighth to twelfth days (14, 18, 20, 27). Patients surviving this interval frequently recover. Whether most patients can be sustained through this interval without the aid of artificial measures such as peritoneal irrigation (6) or the Kolff artificial kidney for in vivo dialysis (13) becomes a very pertinent question. It is our belief that much of the high mortality can be ascribed to the management used and that therefore this question should be answered in the affirmative. It is proposed to present additional evidence supporting such a stand in the form of 3 closely studied previously unreported cases with severe renal insufficiency: 2 following incompatible blood transfusions and 1 following a prolonged operation and hypotension.

CLINICAL COURSE

As previously discussed (27) the clinical course of such cases may be divided into 3 phases.

Phase 1: This is the phase during which renal damage apparently occurs (18, 24, 27, 31). The most common single happening at this time is that of hypotension or circulatory failure. In incompatible transfusion cases this is the phase of acute onset with hemolysis (hemoglobinemia—hemoglobinuria). In the latter event hypotension may be transient but frequently is prominent (27). The hypotension may be associated with mental signs of the shock state (26) or the patient may be quite lucid throughout. In operative cases the anesthetic naturally obscures this latter clinical manifestation.

This is a short lived phase lasting a few hours at most, as the immediate recovery from this phase depends on the recovery from the hypotension or shock state.

Phase 2: The second phase is that of renal insufficiency. Oliguria (or anuria) and azotemia are the outstanding manifestations during

ing this period. In association with the oliguria and azotemia major abnormalities occur

a. **Urinary findings.** Anuria is an infrequent finding in cases without additional complications. The oliguria is very pronounced in severe cases but is seldom fixed in amount. In most cases without water salt overload or other complications there is a gradual increment in the urinary volume during the first 5 to 8 days. Then there usually occurs more prominent daily increments in the urinary output and a peak in the diuresis occurs between the eighth to fourteenth days (average twelfth day).

The urine specific gravity soon becomes fixed at a low range (often 1.005-1.010). The solid output in the urine is very low. Thus the urine urea concentration may be lowered to 10 to 20 per cent of normal and the urinary chloride concentration becomes fixed at low levels. This renal inability to excrete salt has much implication. The combination of oliguria and hyposthenuria makes for negligible renal clearance during this phase.

During the first few days (usually 3 to 5) the urine contains pathologic ingredients. Proteinuria may be quite prominent early being as high as 500 to 1000 milligrams per cent and lowering gradually. The presence of intact red blood cells is not unusual and white cells are usually seen in varying numbers frequently clumped. Casts may be prominent early and are usually granular. Degradation products of hemoglobin or myoglobin may occur within casts depending on the type of case. The heme casts gradually decrease in number during the first week after an incompatible transfusion.

The reaction of the urine is usually acid.

b. **Blood and serum findings.** Azotemia becomes prominent early. It is not unusual for the blood urea concentration to reach 80 to 100 milligrams per cent during the first 2 days and to attain a peak of 300 to 400 milligrams per cent within 5 to 7 days. At the same time there is a distinct tendency toward acidosis as indicated by a decline in the plasma bicarbonate concentration. The blood chlorides and serum sodium concentration are lowered. The hyponatremia may be quite prominent despite a substantial intake of sodium bicarbonate

(see Case 1). The serum potassium concentration may be moderately elevated early, particularly in hemolytic transfusion cases, but in our experience has seldom been very high. Again a moderate intake of potassium is not necessarily attended by a prompt rise in the serum potassium concentration (see Case 1). There are mechanisms therefore that tend to lower the serum sodium and potassium concentrations even with additional intakes of these ions and in the absence of hydemia. Also the hyponatremia and hypochloremia are not necessarily of similar proportions. A significant lowering of the calcium concentration has not been observed in uncomplicated cases. The patients developing this lesion are not infrequently anemic most often a blood loss anemia.

In hemolytic transfusion cases the hemoglobinemia and hemoglobinuria recede during the first 36 hours. The demonstration of met-hemalbumin in the serum by spectrophotometric analysis is considered as clearcut evidence of prominent intravascular hemolysis. An elevated serum bilirubin concentration (or icterus index) may be demonstrated during the first 2 days (Case 2). An additional evidence of incompatible hemolysis is gained by the demonstration of a rising titer of antibodies against cells of the type transfused. The existence of the various orders of antibodies (first second and third) (10) should be searched for in such studies.

c. **Clinical appearance.** There can be little doubt that the clinical appearance of the patient during the first week is greatly influenced by the type of management (27). Patients without added complications particularly water or water salt overload and acidosis, in our experience have not developed the prominent cerebral signs as frequently described. Mental clarity has been observed repeatedly despite severe grades of oliguria for 5 to 8 days. At times, however, the more severe cases have displayed slight mental dullness. Coma or rational loud talk, muscular twitchings and convulsions have been complications in overhydrated cases. Moderate hypertension is a common finding during the renal insufficiency phase. More striking elevations in the blood pressure have been observed in patients with

Fig 1 There are two features depicted the oliguria-diuresis curve and the blood urea concentration (azotemia) Case 1 with anuria and marked oliguria had the peak of the diuresis on the twelfth day Cases 2 and 3 with less marked oliguria had the peak on the eighth and ninth days, respectively The sharp recession in azotemia began with the peak of the diuresis.

a fluid overload Thus 2 patients treated by pentoneal irrigation and displaying definite edema had a blood pressure of 160/110 and 170/90 millimeters of mercury (28) In the former case diuresis was followed by a blood pressure recession to 120/85 millimeters of mercury

Phase 3 The third phase is that of diuresis and constitutes the early period of recovery The diuresis tends to be copious and may be associated with prominent excretion of salt from the body i.e. salt losing diuresis The extent of the diuresis and salt loss seem to be related to the severity of the oliguria of the second phase (compare Case 1 with Cases 2 and 3) The daily salt loss may amount to 20 to 40 grams

After the copious diuresis there is usually a period of prolonged renal convalescence during which polyuria persists The renal clearance may remain depressed for a varying period In a few instances where this feature has been studied by us the renal function returned to near normal within 2 to 4 months

Additional features The urinary volume computed against time in days describes a

characteristic curve that may be designated as the oliguria-diuresis curve In any isolated example the daily plotting of this curve can be used to designate the progress and to yield significant information concerning the prognosis (Fig 1) Thus in cases responding satisfactorily one expects to observe a daily increment in the urine volume and definite diuresis between the eighth and twelfth days The absence of such a trend not only seems to indicate a poor prognosis but may indicate additional complications (27) In our experience attempts to modify this curve by measures which normally stimulate the kidneys to produce urine have failed (27) The characteristics of this curve, apparently based on the functional recovery of the kidneys, correlate well with what is known about the morphologic changes in the kidneys that is alterations that early depict damage and later regeneration and recovery

The ability of the kidneys to regain their concentrating power early seems to be a good prognostic sign In the more advanced cases only rarely does the specific gravity regain a normal or near normal level during the early

phase of recovery. The specific gravity therefore may fail to indicate the true progress. The ability of the kidneys to concentrate urea, on the other hand, seems to be a good prognostic sign (Fig 2). Thus in properly recovering patients it has been observed (27) that the urine urea concentration may change from 10 to 20 per cent of normal during oliguria to 40 to 75 per cent of normal during the diuresis. The concentration of salts in the urine does not appear to be as applicable as a prognostic sign.

RENAL LESIONS

Grossly the kidneys when observed at autopsy are found to be of increased weight not infrequently by a factor of two. Much of the increase in weight seems to be due to a greater water content (12). On section the cut surface bulges and the margins retract, thereby indicating an increased subcapsular tension. The cortex is pale gray and rather friable. The medulla is well striated and purplish in color.

The pyramids are thus made prominent. Microscopically the findings vary in accordance with the time interval since the initial injury. The greatest brunt of the injury is sustained by the distal segment of the nephron. Early (first few days) one may observe degenerative changes and focal necrosis in this segment. The areas of necrosis initiate focal inflammation. There may be tubulovenous connections (15) and partial thrombosis of thin walled veins. Heme cast in this area vary in number and are particularly prominent in hemolytic cases. The glomeruli appear intact morphologically but protein material in the capsular spaces indicates glomerular membrane damage. The proximal segment is the least affected but may demonstrate degenerative changes. Interstitial edema may be prominent. Medullary peritubular venocapillary hyperemia is outstanding. Between the eighth and tenth days regeneration is well advanced (37). The newly regenerated cells are flat but

Fig. 2. Case 1 with a persistent low urine specific gravity (and urine urea concentration) had a prominent salt output during the diuresis. Cases 2 and 3 with normal or near normal urine specific gravity (and urea concentration) had a low salt output during the diuresis. The urine urea output was not as prominent in Case 1 (lower concentration, starvation) as in the 3 other cases (normal concentration, lack of starvation).

soon gain more and more substance. Experimentally (30) by the twenty first day the regenerated epithelium appears near normal. Focal granulomatous lesions and scars may develop. During this recovery phase degenerated epithelial cells and casts apparently gradually creep into the renal pelvis and pass out in the urine.

The morphologic studies demonstrate three important points. First, early there may be not only degeneration but outright necrosis of tubular cells. Second regeneration is well established between the eighth and tenth days. Third a near normal appearance is regained by many tubules by the twenty first day. These pathogenetic changes correlate well with the clinical course. Both clinical and morphologic aspects are taken to possess strong therapeutic implications.

CASE REPORTS

Three additional closely observed cases belonging in this category are being reported. Each patient exhibited distinct signs of renal insufficiency and in accordance with conven-

tional appraisal can be considered to have had a poor prognosis. In each instance there occurred a very satisfactory recovery and each patient was discharged from the hospital in an ambulatory state. It is believed that the satisfactory outcome was implicitly related to the therapeutic management of these patients. In the Discussion the question of "severity" of these cases will be further elaborated. The type of cases are as follows: (1) severe hemorrhages followed by an incompatible (hemolytic) blood transfusion; (2) extensive operation followed by an incompatible (hemolytic) blood transfusion; and (3) an extensive chest operation with multiple periods of hypotension.

CASE 1 (Dr. A. W. Terrell.) A white male 47 years old gave a long history of epigastric distress (10 to 15 years) with intermittent episodes of voluminous vomiting. These episodes usually yielded to medical treatment and rest. Repeated x-ray examinations were said to have demonstrated a large dilated stomach but no definite organic lesion. During the preceding 3 years he had had intermittent hematemesis and black tarry stools.

The present episode began 2 weeks ago and consisted of epigastric discomfort, occasional vomiting and evidence of continual bleeding. Four days ago

the patient was admitted to another hospital and was given two blood transfusions. The first transfusion was uneventful. The second transfusion, 3 days ago was discontinued after about 100 cubic centimeters had been given because of a severe reaction. The onset was sudden with chill headache generalized tingling sensations vomiting and fever. The rate of the blood pressure at the time of the reaction not known. There was no urinary output for 48 hours. On the third day the urine passed (exact amount not known) was dark brown in color. The next urine passed was on the fourth day (90 c.c.). During the first three days, and prior to admission to the present hospital the intake consisted of small amounts of milk water and soup by mouth most of which was said to have been vomited. During the first 12 hours after admission the patient was given 3,000 cubic centimeters of 5 per cent dextrose in distilled water. The subsequent findings are depicted in Table I.

This patient was placed on a regimen which has been described (17). Despite a prominent anemia, it was decided not to give additional transfusions as previously emphasized until later because of a marked anxiety by the patient toward transfusions. The blood pressure was normal and other circulatory features appeared well compensated. Essentially the regimen in this case amounted to (a) an attempt to limit the daily fluid intake to that immediately lost, (b) the prevention of sustained anoxia and, (c) allowing the kidneys to recuperate without any attempt to stimulate them into urine production prematurely.

The attempt to replenish the daily loss was not completely successful as can be determined from Table I. During the 13 days between the fourth and sixteenth days the average daily fluid intake over and above the urinary output (for insensible loss) was 350 cubic centimeters. The latter figure includes the fact that between the ninth and eleventh days there was a definite deficit. It is considered that this volume is short of the actual insensible loss by at least about 50 per cent thus accounting for the minimal signs of extracellular dehydration exhibited by the patient. Despite this deficit the course of the patient was very satisfactory.

The advanced pyloric stenosis prevented the proper oral administration of fluids and nourishment. Between the sixth and seventeenth day an average of 870 cubic centimeters of milk and cream formula were taken orally daily and thereafter about 1000 cubic centimeters of the same formula were taken daily. During the same period the patient averaged a daily intake of 3.6 grams of sodium bicarbonate by mouth all of which was retained. There was an adequate daily intake of vitamin C and B complex.

On this regimen and despite a moderate water deficit the patient had marked diuresis by the twelfth day. Severe oliguria had existed for 6 days. Concomitantly with the diuresis the azotemia abated promptly (Fig. 1). Throughout the entire course the patient was mentally clear and at the height of the

oliguria and azotemia he was able to read periodicals at intervals throughout the day.

In Table I it can be noted that at no time was there severe acidosis. The serum sodium concentration was low early and was elevated to normal levels after the peak of the diuresis was attained. Between the sixth and the ninth days the patient received 23 grams of sodium bicarbonate by mouth and despite having an extracellular water deficit the serum sodium concentration was not elevated to the lower limits of normal at this time. The serum potassium concentration was slightly elevated early. This was perhaps related to the hemolysis. The potassium concentration gradually receded to the normal range. After the fifth day and while renal insufficiency was still prominent the patient received about 1 gram of potassium daily in the milk used in the ulcer regimen. As in the case of sodium, despite this intake of this cation, there was a gradual recession in its concentration as previously noted (17). The blood chloride concentration revealed a pattern similar to that of the serum sodium concentration.

The urine specific gravity (Fig. 2) in this case remained depressed throughout the hospital stay (1.005-1.008). Until the thirty-fourth day the urine urea concentration was likewise depressed (14 to 26 per cent of normal). There was a gradual increase in the daily urinary output of urea and chlorides (as NaCl) until substantial quantities were excreted during the diuresis, mainly as a result of the copiousness of the diuresis. The excretion of sodium and potassium was likewise prominent during this period.

The anemia was marked early. Subsequently as a result of 1300 cubic centimeter transfusions and bone marrow regeneration, the anemia was eradicated.

On the twenty-sixth day because the patient continued to display evidence of severe pyloric obstruction a gastrectomy was performed (Dr. J. V. Goode). The operation lasted 4 hours. Convalescence was rapid and satisfactory and the patient was discharged from the hospital ambulatory 35 days following the reaction. Ten months later the patient was continuing to do well.

In this case there was a severe blood loss anemia and acute renal insufficiency following an incompatible (hemolytic) blood transfusion. The case is appraised as a severe one for the following reasons: (1) marked oliguria for 6 days (2) persistently low specific gravity of urine and low urine urea concentration (3) marked azotemia and (4) peak of diuresis on the twelfth day. The patient recovered very satisfactorily on a regimen which maintained a fair level of hydration but did not attempt to force diuresis. Time was allowed for renal recovery and regeneration. The tendency toward acidosis was curbed with sodium bicarbonate. The diuresis occurred despite a

moderate water deficit. During the diuresis attempts were made to replace the fluid loss in the urine and the insensible loss. As much as 20.5 grams of salt were lost daily in the urine at this time.

It is believed that this case is the first one reported as having undergone very successfully a major operation soon after recovery from severe acute renal insufficiency. That this procedure was justified is attested by the rapid postoperative recovery.

CASE 2 (Dr. W. F. Mengert.) This patient, a 43 year old colored female with a carcinoma of the body of the uterus was seen in another hospital. Two days prior to hysterectomy 500 cubic centimeters of blood was given without any reaction. The operation lasted 5 hours and immediately afterward 500 cubic centimeters of blood were given. Just as the transfusion was terminated the patient developed a severe chill and the temperature rose to 104 degrees F. Later 100 cubic centimeters of cloudy dark brown urine were obtained by catheter. On recheck it was learned that the patient was of type O and the infused blood was of type A.

Prominent oliguria, azotemia, urinary casts, hypertension and hyperbilirubinemia developed (see Table

II). A decrease in serum sodium and blood chloride concentration also occurred.

On the first day the patient received fluid in excess of the immediate needs but this abnormality was corrected by decreasing the intake on the second day. Thereafter the fluid intake was made in equal to the estimated insensible loss through visible sweating and the urinary output. The renal insufficiency phase developed while the environmental temperature fluctuated between 90 and 108 degrees F and consequently the intake was increased accordingly. The fluid intake included 1500 in 2000 cubic centimeters of a liquid formula of low salt content and approximately 1 calorie per cubic centimeter. During the renal insufficiency phase 24 grams of sodium bicarbonate in 6 doses were given and acidosis was not a problem in this case. One 500 cubic centimeter blood transfusion (no reaction) and daily supplements of vitamin B complex and vitamin C constituted the only additional measures.

The urinary output began to rise sharply on the fourth day (Fig. 1) and the peak of diuresis occurred on the eighth day. Beginning on the eighth day there was a precipitous recession of the azotemia. The patient was placed on a soft diet by the seventh day and on a general diet by the ninth day.

In this case there was no anuria and the oliguria was not as prominent as in Case 1. There were three

There are several such preparations available on the market

indications of an early return of the concentrating power of the kidneys. First the urine urea concentration was about 50 to 60 per cent of normal by the fifth day and was 80 to 100 per cent of normal by the eighth day. Consequently during the diuresis large bulks of urea were excreted via the urine (Fig. 1). Second the urine specific gravity was at normal level between the sixth and the ninth day. Third there was a low salt output during the diuresis. On the twelfth day the urea clearance was 70 per cent of normal. The arterial blood pressure was 160/70 on the fourth and sixth days. Between the eleventh and fourteenth days it ranged near 150/90. It then dropped to 130/80 and 120/70 between the eighteenth and twenty-first days. This patient recovered satisfactorily and was progressing nicely 4 months later.

This patient received 500 cubic centimeters of incompatible blood and had an evident severe reaction after all of the blood had been taken. Renal insufficiency with hypertension developed. The hypertension persisted for over 2 weeks. The patient was maintained at near normal hydration and diuresis with recovery occurred in the expected time.

By criteria mentioned by other workers one would have to consider this case as a very severe one. We do not find ourselves in agreement with this view however. It is believed that the early recovery of adequate renal function (early diuresis, concentration power and salt conservation) indicates a less extensive

type of damage. One wonders if the absence of prolonged hypotension in association with the reaction was not a factor in early recovery.

CASE 3. (Dr. D. P. Paulson.) A white male aged 61 years had a resection of the esophagus for carcinoma of the middle third. The stomach was brought up through the diaphragm and a high anastomosis was made with the esophagus. The operation lasted 7½ hours. Anesthesia consisted of ether, nitrous oxide, cyclopropane and oxygen. During the operation 3000 cubic centimeters of blood, 150 cubic centimeters of 3X concentrated plasma and 1000 cubic centimeters of 5 per cent glucose were given. On 4 occasions during the operation the blood pressure was significantly lowered and the pulse pressure was narrowed (70/50 to 90/75). The sum of these periods of hypotension amounted to 80 minutes during the operation. Immediately after the operation was completed the blood pressure was 110/70 millimeters mercury but within 3 hours it became 96/69. After 500 cubic centimeters of blood and 1000 cubic centimeters of glucose solution the blood pressure became normal. On the second day the patient was found to show signs of dehydration with hemoconcentration and mental cloudiness. After 1000 cubic centimeters of glucose solution there was apparent improvement.

It soon became evident that renal insufficiency was prominent (see Table III). Oliguria, azotemia, lowered blood chloride, serum sodium and plasma bicarbonate concentrations developed. The blood pressure became 140/80 millimeters mercury.

The management of this case was very similar to that of Case 2. The blood loss during the operation

was replaced to such an extent (3500 c.c.) that only a slight anemia developed subsequently. During the period of oliguria attempts were made to maintain a fluid intake equal to the estimated insensible water loss plus an amount equal to the urine volume. This attempt was not completely successful. Between the second and eleventh days the patient received an average of 851 cubic centimeters of water per day over and above the volume replacing the urinary volume. At the same time a soft diet and a proprietary high caloric low salt diet were given. Since the environmental temperature was high (summer season) it was obvious that the insensible loss was not completely replaced and that a moderate water deficit developed. This water deficit was of an insufficient proportion to deter the phase of diuretics which occurred in a very similar manner to that of Case 2.

Between the fourth and eighth days 20 grams of sodium bicarbonate were given orally to check the acidotic tendency. Daily vitamin supplements (B complex and C) were administered.

The peak of the diuresis occurred on the ninth day and following this there was a marked recession of the azotemia (Fig. 1). The urine urea concentration and urine specific gravity returned to near normal levels early. As in Case 2 there was a marked urine output during diuresis, associated with a low urea excretion (Fig. 2). Thus during and following diuresis it became necessary to replace water mainly as the salt loss was not great. Recovery from the renal insufficiency occurred. One month later the patient was continuing to do well from the renal standpoint.

The clinical manifestations and course of this case were very similar to those of Case 2. The acute renal insufficiency however, seemed to result mostly from a prolonged operation with an additive prolonged interval of hypotension. In this case as in Case 2 there was an early return of the concentrating power of the kidney and in association with this feature during the diuresis there was a very bulky

urea excretion with a low salt output (Fig. 2). The peak of the diuresis also occurred earlier than in Case 1. It was again demonstrated that the diuresis can develop despite a moderate water deficit.

DISCUSSION

The state of acute renal insufficiency which has been designated as the anoxic kidney "lower nephron nephrosis" and "hemoglobinuria nephrosis" has been attended by a high mortality rate. Commonly encountered complications have been generalized edema, mental aberrations and acidosis. These complications most often have been related to attempts to increase the urinary output during the oliguric period by an excessive intake of water or water and salts. The expected high mortality rate in this group of cases has been markedly lowered by altering the therapeutic approach. Under this proposed management even very severe cases have responded satisfactorily.

The modified management consists of positive measures and has as its basis a combination of morphologic and clinical features. Morphologically it is well established that tubular degeneration with or without focal necrosis of the distal segments is evident early. Tubular recovery and regeneration are definite between the eighth and twelfth days. By the twenty first day morphologic recovery is well advanced. Clinically the cases can be divided into three phases and the management is additionally based on changes occurring during these phases.

The hypotension of the first phase is most often related to oliguria of blood loss type

maintained, it appears that one can afford to wait and allow renal excretion to be the guide in the daily appraisal of the progress of the case. The prevention of severe acidosis may be attained by administering moderate doses of sodium bicarbonate. With the latter the serum sodium concentration is not necessarily rapidly elevated even when a slight extracellular water deficit exists. As emphasized by Maegraith (16) an excess of sodium bicarbonate is to be avoided. It is also of interest that a daily intake of 0.5 to 1 gram of potassium during the renal insufficiency phase in our experience has not been followed by hyperkalemia even when a slight water deficit existed. These findings concerning the serum potassium concentration are not unusual and conform with certain observations made by Keith and others.

Failure to replace water and salts adequately during the diuresis may be associated with complications. Dehydration shock like state, mental aberrations, convulsions may result.

Each phase in the course of this condition seems to be attended by its own therapeutic implications and its own potential complications. Thus deficits and overloads of various fluid compartments may develop under various therapeutic approaches. The mechanisms involved in alterations of various fluid compartments have been well elaborated by Moyer.

As a result of complications related to management relatively milder forms of this condition may be made severe in appearance or even fatal. Thus, attempts to force water or water and salts early in Cases 2 and 3 could have resulted in disastrous sequelae but with the outlined management these cases responded rapidly and satisfactorily.

SUMMARY

The high mortality rate of certain types of acute renal insufficiency may be substantially lowered by altering the therapeutic approach. Three closely observed cases have been presented to lend additional support to this thesis.

The proposed management consists of positive measures based on renal morphologic changes and the main features of the clinical course. There are three main phases, each of

which requires its own therapeutic measures. The hypotension of the first phase is best managed with completely compatible blood. During the second phase (renal insufficiency) a near normal state of hydration is maintained and complete starvation and definite acidosis are prevented as much as possible. During the third phase (diuresis) not only is the water loss replaced but as much as possible a gram for gram salt replacement is made.

The regimen is based on the premise that damaged kidneys require time for healing. Evidences of healing structural and functional appear between the eighth and twelfth days. Survival of properly managed cases through this interval is apparently greatly influenced by the daily betterment of renal function.

Attempts to stimulate the kidneys to produce urine during the oliguric period usually fail. An excessive intake of water or salts over that immediately lost causes an overload of various fluid compartments and upsets existing osmolar concentrations. It is believed that much of the mental aberrations observed early can be attributed to these complications.

The condition is associated with varying grades of severity. Criteria which have been helpful in ascertaining the relative severity have been discussed. That relatively milder cases may be made fatal if not properly managed seems evident.

THE INTRAMURAL EXTENSION OF CARCINOMA OF THE DESCENDING COLON, SIGMOID, AND RECTOSIGMOID

A Pathologic Study

WILLIAM A. BLACK, M.D. and JOHN M. WAUGH, M.D. F.A.C.S. Rochester, Minnesota

THE present-day approach to the cure of carcinoma of the colon is surgical extirpation of the primary lesion and all its extensions with restoration of continuity of the bowel and preservation of sphincteric control whenever feasible.

The importance of carcinoma of the colon is attested by its incidence and cause of death in the general population. The mortality statistics of the Bureau of Census for 1936 give the total death rate from all causes as 1:151.8 per 100,000 population (22). Of these deaths per 100,000 cancer and other malignant tumors cause 111 per 100,000. Of the deaths due to cancer, cancer of the intestines except the duodenum, rectum, and anus accounted for 12 per 100,000 population. Since less than 3 per cent of carcinomas of the intestines originate in the small bowel, the figure for cancer of the intestines represents essentially that for carcinoma of the colon exclusive of the rectum and anus.

Goforth stated that approximately 10 per cent of all carcinomas in the human body and about 96 per cent of all intestinal carcinomas occur in the large intestine and rectum. Azeman, Maydl, Muehler and Nothnagel, in a series of almost 70,000 necropsies, found that 5,796 deaths had been due to carcinoma in general. Almost one-fourth were in the intestinal tract. Rankin, Bargen and Buie quoted Judd's figures on the location of the cancer in the large bowel: There were 159 (25 per cent) in the cecum and ascending colon, 29 (4 per cent) at the hepatic flexure, 75 (10 per cent) in the transverse colon, 24 (3 per cent) at the splenic flexure, 46 (6 per cent) in the descending colon, and 292 (46 per cent) in the sigmoid

Karsner and Clark, in an analysis of 104 cases of carcinoma of the large intestine, found 28 per cent of the lesions in the right portion of the colon, 10.7 per cent in the transverse colon, 16.7 per cent in the descending colon, and 44.4 per cent in the sigmoid. Lockhart Mummery listed the locations of 560 carcinomas of the colon which were essentially the same as those given by Judd: appendix, 0.7 per cent; hepatic and ascending colon, 22.5 per cent; hepatic flexure, transverse colon, and splenic flexure together, 21.6 per cent; descending colon, 5.3 per cent; and sigmoid, 49.8 per cent (19). It can be seen that nearly 50 per cent of carcinomas of the colon occur on the left side. These figures do not include the rectum, which ranks second to the stomach in incidence of carcinoma in the entire gastrointestinal tract.

The purpose of this work was to determine by a pathologic study the extension of any given carcinoma in the long axis of the bowel wall. The study is limited to lesions occurring in the descending colon, including the splenic flexure, sigmoid, and rectosigmoid.

Surgeons dealing with carcinoma of the large intestine have always removed a considerable portion of apparently normal bowel on either side of the carcinoma in order to be sure to include all the extensions of the tumor in the bowel wall. In certain situations especially in the rectosigmoid, it is technically difficult to accomplish wide excision of apparently normal bowel below the lesion and still restore the normal continuity of the bowel. If the surgeon could resect the bowel closer to the primary lesions without leaving malignant tissue behind, operations in which continuity of the bowel is restored, such as anterior resection, would be feasible in a larger number of cases. With this in mind, this study was undertaken to determine the microscopic extension of the carcinoma in the long axis of the bowel.

Abridgment of thesis submitted by Dr. Black to the Faculty of the Graduate School of the University of Minnesota in partial fulfillment of the requirements for the degree of Master of Science in Surgery.
From the Division of Surgery, Mayo Foundation and the Division of Surgery, Mayo Clinic.

Little attention has been paid to the intramural extension of carcinoma of the bowel in its long axis since 1914. Clogg in 1904 studied 25 cases and reported no intramural spread. Cole in 1913 studied 20 cases in which he took longitudinal strips of bowel including the tumor and examined sections microscopically. There was doubtful extension of one colloid carcinoma 14 inches (35.6 cm) from the lesion however in spite of this he concluded that the typical intramural spread was wedge shaped with the apex the lesion itself and the base, the serosa. The extension was slight but equal above and below the lesion. Cheate, in 1914 in a similar study of his own cases reported no longitudinal spread of carcinoma. Monsarrat and Williams, in a study of rectal carcinoma found evidence of longitudinal spread 23½ inches (57 cm) from the lesion in 1 case but for the most part the distance of spread was less than 1 inch (2.5 cm). He also noted that infiltration was widest in the plane of the longitudinal muscle coat. Miles (16) noted that spread of cancer in the submucosa extended no more than a few lines from the mucosal growth and that the spread in the deeper layers was just as limited. Lockhart Mummery observed that spread of carcinoma by infiltration through the rectal wall was characteristically greater in the submucosa than in the mucosa and this is borne out by our study. Dukes (9) stated that the opinion as to spread by direct continuity based on gross examination will not be altered much by the microscopic examination.

Several classifications based on the intramural and extramural spread of carcinoma of the rectum have been devised. The best known is that of Dukes (9). He classified the carcinomas into three groups. In group A he placed those growths which are limited to the wall of the rectum. In group B those which have extended into the extrarectal tissues but have not metastasized to the regional lymph nodes and in group C those which have metastasized to the regional lymph nodes (13). Simpson and Mayo classified carcinoma of the rectum according to the depth of penetration through the bowel wall. Group A included those lesions which are limited to the mucosa. Group B those lesions which penetrate to the

submucosa and group C, those lesions which penetrate to the serosa. Such classifications are useful in determining the prognosis. In cases of lesions in group A the prognosis is best and in group C, the worst.

METHODS OF SPREAD OF CARCINOMA

Although the original work in this paper deals only with the spread of carcinoma in the bowel wall, a brief review of all methods of spread is indicated.

Carcinoma of the colon spreads in 3 ways (1) by local extension from its origin (2) by invasion of the venous system and (3) by means of the lymphatics.

Local extension. Most carcinomas of the colon are slow growing. They take their origin from altered mucosal cells deep in the crypts of Lieberkuhn. Welch thought that mucosal spread is by contact and that some stimulus from the cancer cell be it chemical, virus, or other acts on the cells adjacent. The spread through the layers of the bowel wall is by infiltration. The muscle is penetrated by rootlike projections between the bundles of muscles. Lockhart Mummery and Dukes (8) stated that ulceration usually begins when the muscular layer is reached due to interference with the blood supply at the surface and local sepsis.

Venous spread. Invasion of the venous channels may occur at any stage in the development of the carcinoma. When this occurs the formation of malignant thrombi and dispersion of malignant emboli make complete removal of the carcinoma impossible. The lesion most commonly spreads through the portal system to the liver. The work of Batson on the function of the vertebral veins with their anastomoses with the portal system explains the occasional occurrence of metastatic lesions in bone especially the sacrum, coccyx, and lumbar vertebrae. Studies by Collier, Kay and MacIntyre, Seefeld and Bergen, and Dukes and Bussey have shown that intravascular invasion occurs in 15 to 20 per cent of malignant lesions of the colon. Seefeld and Bergen showed that the incidence of venous invasion increased as the grade of malignancy (Broders' method) and the extent of mural penetration increased. Visceral metastasis is not always present when

Fig. 1 Intramural lymphatic system of the colon. Graphic presentation of Cole's description.

evidence of venous involvement is found. Dukes and Bussey were unable to find other metastatic involvement at necropsy in 10 of 13 cases in which the veins were invaded.

Lymphatic system. The importance of spread of carcinoma in all parts of the body through the lymphatic system has long been recognized. All operations employed for extirpation of malignant growths in the colon are designed to include removal of the lymphatics that drain the region of involvement. The lymphatic system of the colon can be divided into the extramural (serosa to regional lymph nodes) and intramural (mucosa to serosa) components.

The anatomy of the extramural lymphatics was best described by Delamere, Poirer and Cunéo. The lymphatics of the ilio pelvic portion of the colon at first traverse some small glands which are attached to the terminal branches given off by the paraintestinal arch and formed by the anastomosis of the three sigmoid arteries. They then terminate in glands placed over the inferior mesenteric artery. The lymphatic vessels of the descending colon present an arrangement similar to that of those in the ilio pelvic portion of the colon. In other words, the extramural lymphatics of the left portion of the colon are situated along the arteries to that region. Recent work by Glover and Waugh has shown that the spread of carcinoma of the rectum and rectosigmoid through these lymphatics is upward in 99 per cent of the cases.

The anatomy of the intramural lymphatics was best described by Cole (Fig. 1). The lymphatics of the mucosa do not exist as a continuous plexus but are arranged as decussating branches from the collecting stems which pierce the circular muscular coat. The intermuscular lymphatics are similarly limited

Small branches situated between the muscle coats drain into collecting stems which empty into subserous plexuses. From here the drainage is to the paracolic lymph glands which are a part of the extramural lymphatic system.

STUDY OF 103 SPECIMENS

Materials and method. The materials used in this study were 103 specimens of bowel removed at operation at the Mayo Clinic. A few criteria were used in their selection: the lesion had to be in the descending colon including

Fig. 2 Position of blocks removed from specimens.

Fig. 3. The edge or base point of the lesion.

the splenic flexure, the sigmoid or rectosigmoid and at least 1 inch (2.5 cm.) of grossly normal bowel had to be present above and below the carcinoma. Specimens were selected so that lesions of all four grades of malignancy (Broders' method) were included in the study.

Each specimen was subjected to the following examination: blocks of tissue through the entire bowel wall were removed above and below the lesion in such a manner that the edge of the tumor was included with the normal bowel (Fig. 2) frozen and paraffin sections of blocks were made; all sections were stained in the usual manner with hematoxylin and eosin and subjected to careful microscopic examination.

The examination of the slides was carried out in the following manner: the edge or base point of the lesion was marked on the slides; the limit of extension of the carcinoma was marked on the slide and the distance from the base point was measured in millimeters; the greatest depth of penetration through the bowel wall was noted; the layer of the bowel wall in which the farthest extension had occurred was noted; and finally the malignancy of

the tumors was graded according to the method of Broders.

The edge or base point of the lesion is illustrated in Figure 3. It was felt that the cauliflower or overlying free edge of the tumor was movable and therefore inconstant on palpation so that it should not be used for measurement. Consequently, the base of this free edge was chosen as the base point of the lesion.

The carcinoma was followed out to the point of greatest extension from the lesion (Fig. 4). This point was marked on the slide and the distance between the two points was measured in millimeters. The layer in which maximal extension had occurred was noted as well as the layer of deepest penetration through the bowel wall.

All tumors were graded independently by the author and then checked with the grade reported by the pathologist at the time of removal. This grading corresponded well with the reported grades, and in those instances in which a difference occurred these specimens were checked by Dr. John R. McDonald of the section on surgical pathology of the clinic. Table I shows the grades of the carcinomas.

studied and the location of the lesion in the bowel

Information was available regarding the presence or absence of involvement of lymph nodes from the pathologic reports on the fresh specimens. This information was accepted without further study of the specimen. Table II shows the percentage of cases in which lymph nodes were involved for each location. These figures are probably low since all the nodes in each specimen removed were not examined microscopically. This information is presented only to show that the short distance of intramural spread which was found cannot be explained on the basis of early lesions or the

low-grade invasive power of the tumors studied.

Results The results of this study are best discussed under the following headings: (1) extension by plane of the bowel wall, (2) depth of penetration through the bowel wall, and (3) relation of involvement of lymph nodes to depth of penetration.

Extension by plane of the bowel wall.—The spread of carcinoma in the mucosa ended abruptly and was marked by the raised edge of the lesion. Figure 5 illustrates this phenomenon. In this photomicrograph the normal mucosa can be seen extending up the raised edge of the carcinoma even though a clump of malignant cells lies directly beneath

Fig. 5. Carcinoma, grade 4, showing mucosal and submucosal spread. $\times 75$.

Spread in the submucosa was characterized by large masses of carcinoma cells pushing the muscular layers away from the mucosa and increasing the thickness of the bowel wall in the region of the gross lesion. Extension longitudinally under the mucosa was characterized by small islands of carcinoma cells infiltrating the loose submucosal tissues to varying distances and usually surrounded by aggregates of lymphoid cells. The thickness of the bowel wall was not increased. In Figure 5 a small island of carcinoma cells is seen under the villus just to the right of the raised edge of the lesion. The upper diagram in Figure 4 illustrates the submucosal spread under normal mucous membrane. The shaded areas represent carcinomatous infiltration. Note that though the longitudinal spread is greatest in the submucosa the carcinoma has infiltrated to the serosa. Maximal extension occurred in this layer in 50 per cent of all the specimens examined.

The spread through the muscular layer was characterized by incomplete columns of carcinoma cells radiating down between the muscle bundles. This suggests that the spread fol-

TABLE III.—LAYER OF BOWEL WALL IN WHICH GREATEST SPREAD OCCURRED

Layer of bowel wall	Descending colon		Sigmoid		Rectosigmoid	
	Specimens		Specimens		Specimens

Circular muscle	3				4	5
Longitudinal muscle	7		3		5	
Serosa			4			

lows the paths of the intermuscular lymphatics. Figure 6 illustrates the extension of a grade 1 adenocarcinoma through the muscular layers. Maximal extension occurred in these layers in 26 per cent of all the specimens examined. The middle diagram in Figure 4 illustrates the usual spread of carcinoma through the muscular layers.

In the serosa extension was characterized by small dispersed groups of carcinoma cells situated usually in the subserous layer and surrounded by clumps of lymphoid cells. Figure 7 shows a group of grade 4 carcinoma cells in the subserous layer. The lower diagram in Figure 4 illustrates by the shaded areas the typical spread when the greatest longitudinal extension occurs in the serosal layer. Maximal extension occurred in this layer in 24 per cent of all the specimens.

In Table III are summarized the findings concerning the plane of the bowel wall in which maximal extension occurred for each of the locations in the colon from which specimens were examined. The percentage occurrence in each location is recorded.

No appreciable difference was noted in extension above or below the lesion. The greatest longitudinal extension in any specimen was 12 millimeters and in only 4 of the total number of specimens was the spread 5 millimeters

TABLE IV.—EXTENSION OF CARCINOMA

Location	Minimal	Maximal	Average
	Millimeters		
Descending colon	less than		
Sigmoid	less than		50
Rectosigmoid	less than	5	

Fig. 6. Carcinoma, grade 1 infiltrating the muscular layers of colon

Fig. 7. Carcinoma, grade 4 infiltrating in subserous layer of colon

or more. All of these were located in the descending colon. This would indicate that greater extension occurs in this location in the bowel. In Table IV the minimal, maximal, and average distance of spread of carcinoma for the three locations studied are listed.

The grade of carcinoma had no relation to the intramural spread. Of all the grade 4 carcinomas studied, only one or 7.6 per cent had extended more than 5 millimeters. The lesion which had spread a distance of 12 millimeters was a grade 1 adenocarcinoma.

Depth of penetration.—The depth of penetration through the bowel wall had no relation to the longitudinal spread. The serosa was involved in 37 per cent of all the specimens examined. In all these specimens the greatest longitudinal extension occurred in a layer nearer the mucosa. These findings vary with the contention of Miles (16) that intramural spread is wedge shaped with the apex at the

mucosa. In Table V are summarized the findings concerning the plane of deepest penetration through the bowel wall for each location in the colon and the percentage occurrence for the different locations.

Relation of involvement of lymph nodes to depth of penetration.—Lymph nodes are involved before the carcinoma penetrates through the bowel wall. Of the 48 specimens in which lymph nodes were involved, the depth of penetration through the bowel wall in 24 or 50 per cent, of the specimens was not to the serosa. These findings support the contention of Miles (16, 17) that metastasis to the lymph nodes occurs before the bowel wall is penetrated and are at variance with Dukes' (9) assumption that lymph nodes are not involved until the bowel wall is penetrated.

CONCLUSIONS

1. In carcinoma of the colon the raised edge of the lesion may not mark the limit of intramural extension.

2. There is no appreciable difference in intramural spread of carcinoma above or below the lesion.

3. Intramural spread of carcinoma is greater in the descending colon than in other sites in the left portion of the colon.

4. The plane of greatest extension in the bowel wall is the submucosa.

5. The grade of malignancy (Broders' method) of the lesion has no relation to the degree of intramural spread.

TABLE V.—LAYER OF DEEPEST PENETRATION OF BOWEL WALL

Layer of bowel wall	Descending colon		Sigmoid		Rectosigmoid	
	Specimens		Specimens		Specimens	
	Number	Per cent	Number	Per cent	Number	Per cent
Submucosa	13	26	3	15.2	3	17.6
Circular muscle	7	4	6	5.9	6	33.3
Longitudinal muscle	8	16	1	2.8	4	22.2
Serosa		4	25	44		11.1

6 Spread of carcinoma through the bowel wall appears to follow the course of the intramural lymphatics

7 Spread of carcinoma to the extramural lymphatics occurs before the entire bowel wall is penetrated

8 For resection of the left part of the colon for carcinoma only 2 centimeters of normal bowel need be allowed above and below the lesion in order to remove the whole of the primary lesion

STUDIES ON VAGOTOMY IN THE TREATMENT OF PEPTIC ULCER

IV Changes in Gastric Motility and the Effect of Drugs on Motility Following Complete Vagotomy

I F STEIN Jr., M.S. M.D. KARL A. MEYER, M.D. F.A.C.S. and
FREDERICK STEIGMANN M.D., F.A.C.P. Chicago, Illinois

THE history of vagotomy and its use in the treatment of peptic ulcer have been recently reviewed (15-18). It is likely that all of the procedures used in man by the early workers in this field resulted in only partial vagus section. Drag-

stedt's introduction of complete vagotomy as a treatment for peptic ulcer in 1943 (2) has caused renewed interest in the subject.

In June of 1946 a clinical and physiological study of vagotomy in the treatment of peptic ulcer was started on one of the surgical services at the Cook County Hospital (K.A.M.). During the following year vagus section was carried out in 35 cases of peptic ulcer in which definite indications for surgery were present.

From the Heltoen Institute for Medical Research of the Cook County Hospital and from the Departments of Surgery of the Cook County Hospital and Northwestern University Medical School.
Dr. Stein is Abbott Fellow in Surgery, Northwestern University Medical School.

Fig. 1. Gastric motility tracing before vagotomy showing spontaneous and insulin induced hunger contractions.

The gastric motility tracing following complete vagotomy showing no spontaneous or insulin induced gastric contractions

These patients were thoroughly studied both before and after surgery. A clinical evaluation of this series (9) and results of the physiological studies (10) are published elsewhere. The present report is concerned primarily with the changes in gastric motility and the effects of drugs on gastric motility following complete vagotomy.

Early in our series, 1 of the patients developed an acute gastric retention and dilatation on the 10th postoperative day. This complication aroused our interest in the use of drugs to stimulate gastric emptying after vagotomy.

The therapeutic use of choline esters has been previously studied. The subject has been reviewed by Starr and Ferguson and Goodman and Gilman (5). Youmans demonstrated experimentally the stimulatory effect of urecholine on intestinal motility. Recently Machella, Smith, Grimson and Dragstedt (3) have reported on the use of urecholine in the

treatment of gastric retention following vagotomy. We have previously confirmed this use of urecholine and have reported a similar action of doryl (20). Postlethwait has compared the action of neostigmine, mecholyl, doryl and urecholine on the intestine of the rabbit.

METHOD

The motility of the stomach was determined after 16 to 24 hours of fasting by passing a tube into the stomach with a 200 cubic centimeter balloon attached. The balloon was placed high in the fundus of the stomach and its position verified by inflation and gentle withdrawal until a slight tug was felt as the balloon reached the cardiac end of the stomach. The balloon was then partially inflated with 10 to 50 cubic centimeters of air and connected to a water manometer. Recordings were made on a slowly moving kymograph. An average of 10 hours of tracings was made on each of 27 patients.

Fig. 3. Postoperative motility tracing showing the effect of 3.0 milligrams of doryl by mouth.

After the spontaneous fasting motility had been determined for 1 to 3 hours, the effect of the following drugs was noted insulin, doryl urecholine prostigmine and mecholyl. In most instances only 1 drug was tested per day in order that a possible synergistic effect would not confuse the results.

RESULTS

Before vagotomy all 27 patients showed spontaneous type I and occasionally type II and III hunger contractions (1) (Fig 1). Following complete vagotomy, as determined by the insulin test, 24 patients had no spontaneous hunger contractions in the fundus of the stomach after 16 to 24 hours of fasting. Tonus rhythm was noted but no hunger contractions were present (Fig 2). The patients were studied 10 days to 2 weeks after surgery. Seven of 8 patients studied 3 to 9 months later had no spontaneous hunger contractions. An

insulin test in the eighth case showed return of vagus function after 9 months. Spontaneous hunger contractions were present in the fundus of the stomach.

After incomplete vagotomy as determined by the insulin test, spontaneous type I or type II hunger contractions were noted in 2 of 3 cases.

Effect of insulin Before vagotomy insulin hypoglycemia was usually followed by a period of hypermotility (Fig 1). After complete vagotomy in 24 cases there were no hunger contractions in the fundus of the stomach following insulin hypoglycemia (Fig 2). After incomplete vagus section in each of 3 cases insulin hypoglycemia was followed by hunger contractions.

A detailed discussion of the effect of insulin hypoglycemia on the stomach and its use in this study as a test after vagotomy has been reported (18).

Fig. 4. Barium meal 2 weeks after vagotomy had been carried out

Fig. 5. Same as Figure 4, 5 minutes after the administration of 0.5 milligram of doryl subcutaneously

TABLE I.—THE EFFECT OF DRUGS ON GASTRIC MOTILITY AFTER COMPLETE VAGOTOMY

Drug	Dose Milligram	No. of tests	Results		
			No effect	Increased motility	
				Slight	Marked
Carbamylcholine (doryl)	25 subcut				2
	2-4 orally	9			5
	sublingually	(20)			
Urethane of B-methylcholine (urecholine)	5 subcut	3			3
	20 orally	8	3		3
	20 sublingually	()			
Doryl and urecholine	plus orally	3			3
Prostigmine	25 m				
	5 m				
	5 orally				
	20 orally	4	4		
	45 orally	(15)			
Macholyl	200 orally plus				
	200 orally				

The effects of doryl urecholine, prostigmine, and macholyl on gastric motility after complete vagotomy are summarized in Table I.

Effect of doryl (carbamylcholine) The administration of doryl 2 to 4 milligrams orally (Fig. 3) or 0.25 milligram subcutaneously (Figs. 4, 5) was usually followed by a marked increase in gastric motility.

Following oral administration, the increased motility was noted from $\frac{1}{2}$ hour to $1\frac{1}{2}$ hours later and lasted from 30 minutes to 3 or more hours. Following subcutaneous injection, the increased motility was noted in 5 to 10 minutes and lasted 30 minutes to 1 hour. There were no serious toxic effects although occasionally sweating salivation or abdominal cramps were noted. Two tests were terminated when 2.0 milligrams of doryl given orally produced no change in gastric motility in 1 hour. It was later determined that the stimulatory effect may not be noted for $1\frac{1}{2}$ hours. This may have been the case in these tests, listed in Table I as No effect.

Effect of urecholine (urethane of B-methylcholine) The administration of 5.0 milligrams of urecholine subcutaneously was followed by

Fig. 6 Postoperative motility tracing showing the effect of 0.06 milligrams of urecholine by mouth.

increased gastric motility in 10 minutes, lasting 30 minutes to 1 hour. Ten milligrams by mouth usually produced increased gastric motility in 30 minutes to 1½ hours lasting 30 minutes to 3 or more hours (Fig 6). There were no serious toxic effects, although a few instances of sweating or abdominal cramps were noted.

Combined effect of doryl and urecholine. Two milligrams of doryl were given by mouth and 45 minutes to 1 hour later 10.0 milligrams of urecholine were given orally. A marked increase in gastric motility was noted soon after the urecholine was given, lasting at least 3 hours (Fig 7). There were no serious toxic effects.

Effect of prostigmine. In only 1 instance of 11 trials did prostigmine produce any change in the gastric motility. In this case 45.0 milligrams by mouth produced a marked increase in motility associated with severe abdominal

cramps. The intravenous injection of 0.6 milligram of atropine sulfate caused immediate cessation of both the cramps and increased gastric motility.

Effect of mecholyl. In 2 instances 200.0 milligrams of mecholyl by mouth produced no change in gastric motility. A second dose of 200 milligrams was given once at the end of 1 hour without effect.

X ray studies. A detailed report of these studies is to be published elsewhere (17). In general 2 weeks after complete vagotomy there was a marked delay in gastric emptying with a 50 to 70 per cent retention of barium in 4 hours. A gastroenterostomy was performed on 25 of the patients. In 8 instances it was done as part of previous surgical procedures in patients who later developed marginal ulcers. Gastric retention was present in patients with and without gastroenterostomy, but was greater in the latter group. Delay in emptying was less

Fig. 7 Postoperative motility tracing showing the combined effect of milligrams of doryl and milligrams of urecholine by mouth.

marked after 3 months however after 9 months, delayed emptying was still present

DISCUSSION

Following complete vagus section there is a marked reduction of gastric motility and a prolongation of gastric emptying time. Early in this study oral feedings were started on the third or fourth postoperative day but following the case of gastric retention and dilatation mentioned earlier the regimen was changed to prevent any early distention of the stomach. Postoperatively continuous intragastric suction and parenteral fluids were maintained for 3 days. On the 6th and 7th days small feedings of clear liquids were given and on the 8th and 9th days small feedings of a general liquid diet were given. A soft diet was usually allowed on the 10th day. Since the postoperative care was changed delayed gastric emptying was still noted, but was less marked. To only a few

patients did symptoms of gastric distention require the therapeutic use of doryl or urecholine and no further cases of acute retention and dilatation were encountered. When used therapeutically either 2.0 to 4.0 milligrams of doryl or 10.0 milligrams of urecholine were given by mouth three times a day before meals. Parenteral administration either 0.25 milligram of doryl or 5.0 milligrams of urecholine subcutaneously was sometimes used first.

Additional treatment was unnecessary after a few days to a week. The patient who had acute gastric retention and dilatation previously mentioned was an exception and required more prolonged therapy. This patient had partial gastric retention after 24 hours and complained of foul belching. Treatment with doryl or urecholine was continued for 5 months after which time the patient was asymptomatic, although gastric emptying was still markedly delayed.

We have observed that both doryl and urecholine cause an increase in gastric acidity as well as an increase in motility. This stimulatory effect on gastric secretion of doryl has been previously noted by Noll and Goodman (4) and of urecholine by Machella. Recurrence of ulcer symptoms has not been noted in patients receiving these drugs either experimentally or therapeutically.

The pharmacological action of doryl and urecholine has been studied and reviewed by Starr and Ferguson. They conclude that although the therapeutic usefulness of the two drugs is similar, doryl has a much stronger nicotinic-like action than urecholine and is therefore more toxic.

Following complete vagus section, doryl or urecholine produces gastric motility simulating normal type I or type II hunger contractions, as well as increase in gastric tone. These hunger contractions differ from normal spontaneous hunger contractions in that they are more frequent and more regular but are of smaller amplitude.

SUMMARY AND CONCLUSIONS

The gastric motility of 27 patients with peptic ulcer has been studied before and after vagus section. By the method of motility study described it has been shown that no spontaneous or insulin induced type I, II, or III hunger contractions are present in the fundus of the stomach up to 9 months after complete vagotomy. There is a marked delay in gastric emptying following complete vagotomy. Delayed emptying is still present after 9 months. After incomplete vagus section hunger contractions are present either spontaneously or following insulin hypoglycemia.

Doryl 0.25 milligram subcutaneously or urecholine 5.0 milligrams subcutaneously,

produces a rapid but transitory increase in gastric tone and motility following complete vagotomy. The oral administration of doryl, 2.0 to 4.0 milligrams or urecholine 10.0 milligrams usually produces a more sustained increase in gastric tone and motility after complete vagus section. Prostigmine and meclocholyl have little if any effect on gastric motility after complete vagotomy.

INTRAPERITONEAL PRESSURE IN THE HUMAN

JAMES C DRYE, B.S. M.D., Louisville, Kentucky

INTRAPERITONEAL pressure is one of the stresses thrown on a healing abdominal incision. This work was undertaken to measure intraperitoneal pressure and to determine the effect of such factors as position, movement, coughing, straining, and early ambulation.

In the literature there has been considerable controversy concerning intra abdominal pressure in humans. Emerson reviewed the literature in 1911 and found that a number of investigators reported a negative pressure and an equal number reported a positive pressure. From the rather scant details of this paper it seems that those reporting positive pressure had introduced balloons into the body orifices and those reporting negative pressures had introduced needles or trochars into the peritoneal cavity. Overholt and Lam pointed out that in a peritoneal cavity containing no free gas or fluid only a negative pressure will be registered when a needle or trochar is introduced as nothing enters the needle or trochar.

Overholt in 1931, Lam in 1939, and Rushmer in 1946 studied the abdominal pressure in animals using balloons introduced into the peritoneal cavity and agreed that intraperitoneal pressure is hydrostatic and depends on the position of the animal and on the vertical level at which pressure is measured.

It seemed to us that intraperitoneal pressure in humans could be accurately measured by balloons introduced into the peritoneal cavity and that these could be introduced and left without harm at the end of such abdominal operations as those requiring drains and in those for penetrating abdominal wounds. No harm has occurred to any patient so studied.

METHODS

A rubber condom was cut off at its open end so as to hold 60 to 100 cubic centimeters of air

From the Department of Surgery, University of Louisville School of Medicine.

Presented at the Forum on Fundamental Surgical Problems before the Clinical Congress of the American College of Surgeons, New York, September 8-11, 1947.

without resistance and was tied over the end of a urethral catheter. The catheter was brought out through a stab wound and in the earlier experiments the balloon was placed free in the peritoneal cavity. It was found that the balloon gravitated to the pelvis, so in later experiments the position of the balloon was fixed by a suture passed through the abdominal wall around the catheter near the balloon and tied outside. In some cases two balloons were introduced, one in the upper abdomen and one in the lower. The position of all balloons was checked by roentgenograms.

Pressure was measured by a U manometer containing water or bromoform. The latter is a heavy fluid and was used in recording the higher pressures. All pressures are reported in centimeters of water. To measure the intraperitoneal pressure the balloon was first inflated with air to its full capacity of 60 to 100 cubic centimeters. It was then completely emptied and 5 cubic centimeters injected at a time and the pressure recorded. It was usually found that any volume between 5 and 25 cubic centimeters could be injected without varying the pressure more than 1 centimeter of water. In all cases an amount was injected so that 5 to 10 cubic centimeters more or less caused a change of pressure less than 1 centimeter of water.

In some cases the pressure was read off the manometer; in others kymograph tracings were made.

RESULTS

With the subject supine the intraperitoneal pressure was found to average 8 centimeters of water in 9 patients with 30 separate recordings and there was no difference in pressure in the upper and lower abdomen (Fig. 1). With the subject erect the pressure in the upper abdomen was found to remain about the same. In the lower abdomen the pressure increased almost 3 times its supine value (Fig. 2). In one subject in which the upper balloon was located just beneath the dome of the left dia-

Fig 1. Intrapertoneal pressure with patient at rest in supine position. \times , Lower abdomen; \circ , upper abdomen. Average pressure: upper abdomen, 8 centimeters of water; lower abdomen, 7.5 centimeters of water.

Fig 2. Intrapertoneal pressure with patient at rest in erect position. \times , Lower abdomen; \circ , upper abdomen. Average pressure: upper abdomen, 7 centimeters of water; lower abdomen, 10 centimeters of water.

phragm the pressure actually dropped a little (Fig 3).

In comparing pressures taken at two different vertical levels by using two balloons in the same peritoneal cavity, it was found that the greater the distance between the vertical levels the greater the difference in pressure (Fig 4). The relationship is closer than shown as the distances were simply measured off as shown on an x ray film taken at 36 inches which magnified the distance. This confirms the findings of Lam Overholt and Rushmer who from data in animals concluded that intraperitoneal pressure was a hydrostatic one

EFFECT OF EFFORT

The most marked increases were due to coughing and vomiting. One patient (J P) with a hard cough blew the fluid out of a manometer with a limit of 150 centimeters. This was partly overshoot but since another patient (C J) maintained a pressure of 80 centimeters while retching we feel that the 150 was not unreasonable (Table I).

Table I shows the average actual pressures attained and the average increases over supine pressures in various activities. The pressure attained in getting out of bed (29 cm) and

Fig 3. Effect of posture on intraperitoneal pressure. Upper balloon just beneath left diaphragm. Change of position on electrically driven tilt table T.L. Fourth day after operation.

Fig. 4. Difference in pressure at different vertical levels with patient in the erect position. White space, distance between upper and lower balloons. Cross-hatched space, difference in pressure (cm. of water) in upper and lower balloons. F.W. upper balloon just below superior spine of ilium. walking (18 cm) does not approach the pressure increase in such unavoidable activities as vomiting (80 cm) and coughing (62 cm) when supine. The highest single pressure recording as was mentioned before was 150 centimeters attained on coughing.

The intensity of effort in such a voluntary act as straining at stool can be controlled by the patient and it is probable that he can partly control the intensity of such acts as getting out of bed. A patient with little pain is more likely to strain and cough hard and to

TABLE I.—EFFECT OF EFFORT ON INTRAPERITONEAL PRESSURE

(Cm. W. ter)

	Average		
	Actual pressure	Increase over supine pressure	No. patients
Side-Fowler position		4	3
Full Fowler position	14	5	
Arising from bed to standing	20	20	6
Walking	6		3
Sitting in chair	7	6	6
Getting into bed	26		
Getting on bedpan	9	9	
Vomiting while on bedpan	5	3	3
Defecation while on commode	24	12	
Straining at stool while on commode		52	3
Coughing	6	52	6
Vomiting	80	72	

move abruptly. These factors affect the intraperitoneal pressure. However it is seen in Table I that on an average the acts of straining at stool, getting on bedpan, and defecating cause about the same increase as getting out of bed and walking.

It must be remembered however that intraperitoneal pressure is only one of the stresses thrown on an abdominal wound, the other most important one being muscle pull. It is

Fig. 5. Effect of effort and posture on intraperitoneal pressure. Balloon located just to left of umbilicus. J.P. Third day after operation.

likely that the abdominal muscles can be strongly contracted without greatly increasing the intraperitoneal pressure. However from the above data we can say that the increase of intraperitoneal pressure due to walking and rising does not throw a significant stress on the healing wound.

EFFECT OF ABDOMINAL DISTENTION

It is difficult to assess abdominal distention. In the 1 patient (W F) whose abdomen was definitely but not severely distended the supine intraperitoneal pressure was 1 centimeters. It seems reasonable to assume that a large amount of intestinal gas would increase the intraperitoneal pressure.

EFFECT OF RESPIRATION

In general there were fluctuations of pressure of 2 to 4 centimeters with respiration. In 2 patients in which the pressure was read from the manometer the intraperitoneal pressure decreased on inspiration. On all those in which kymograph tracings were made and simultaneous ordinants obtained the pressure rose on inspiration. It is suggested that the type of fluctuation depends on the predominance of the type of respiration, i.e. diaphragmatic or intercostal. Overholt found this to be true in animals.

EFFECT OF PNEUMOPERITONEUM

We do not believe that the amount of air introduced into the peritoneal cavity at the time of operation was significant in our work. In measurements taken over a period of a week there was no progressive decrease in pressure as the air was absorbed.

Further it was found that when 40 to 70 cubic centimeters of air was injected into one of two balloons in a peritoneal cavity the pressure in the other balloon did not change. More air was not injected because of the pro-

duction of pain. This same experiment was carried out in 2 patients.

CONCLUSIONS

- 1 A safe accurate method of measuring intraperitoneal pressure in humans is presented.
- 2 Intraperitoneal pressure has been studied in the human during the first postoperative week.
- 3 In the supine position the intraperitoneal pressure is about 8 centimeters of water in both the upper and lower abdomen.
- 4 In the erect position the pressure in the upper abdomen is about 8 centimeters of water. The pressure in the lower abdomen is about 20 centimeters of water. The greater the vertical distance between the two points measured the greater is the difference in pressure.
- 5 Involuntary action such as coughing, vomiting and straining at stool elevates the pressure to levels as high as 80 centimeters of water which is a much greater elevation than that caused by arising and walking.
- 6 Early ambulation does not increase the intraperitoneal pressure enough to make it a significant stress on the abdominal incision.

NOTE.—Our interest in intraperitoneal pressure was stimulated not only by the apparent advantages of early ambulation but also by a personal experience in 1941 following a right inguinal herniorrhaphy. My own experience with early ambulation at the time demonstrated that patients had much less pain in the incision when attempting to void in the erect position or defecate on the toilet than when attempting to perform either of these functions in the supine position in bed. The pain in the incision was quite obviously due to contraction of the abdominal muscles in an attempt to increase intra-abdominal pressure and it was apparent that, in the erect position patients had much less tension on the incision than when lying flat in bed. This impression has, I believe, been confirmed by Dr. Drye's experiments.

THE SURGICAL SIGNIFICANCE OF INDETERMINATE PUL- MONARY LESIONS

THE development of curative surgical treatment for lesions within the chest has been almost entirely accomplished within the past three decades. Prior to that time intrathoracic surgery consisted chiefly of the drainage of infections. The diagnosis of lesions within the thorax began somewhat earlier and was enhanced by the discovery of the x ray by Roentgen in 1895 and the use of the bronchoscope by Killian in 1897. These diagnostic aids for a time set the pace for therapy. In recent years, however, adequate anesthesia, blood and other parenteral fluid therapy, chemotherapy, and the development and improvement in surgical technique have advanced surgical management to a very high degree. This stage of development was forecast by Adler in 1912 when he wrote: "There is every reason to hope that the technique of this new branch of surgery will be still further developed and that in the near future thoraco-

tomy and operations on the lungs will be attended by no more risk than peritoneal operations today. When all the means of diagnosis outlined in this little study fail where there are suspicions of tumor but no assurance is possible, there should be—it is emphatically here stated—as little hesitation in resorting to an exploratory thoracotomy as there is now in submitting to an exploratory laparotomy." That the risk of exploring the thorax is now very little when the fundamental principles are observed is most fortunate, since in spite of many improvements in diagnostic methods there still remains a considerable proportion of inflammatory, neoplastic, and congenital intrathoracic lesions which defy all attempts at diagnosis.

In the earlier course of the development of this field of surgery, when the operative approach was made with considerable hesitation and risk, diagnosis depended to a considerable extent on the clinical history and findings. Refinements in x ray diagnosis awaited further development and recognition of the lesion was not forthcoming until an advanced stage had been reached. Unfortunately, all too frequently this delay necessitated a much more radical type of surgery, if indeed more than an exploratory thoracotomy could be performed.

Although the clinical history and findings continue to play an important part in diagnosis, they frequently fall far short of an adequate means on which to base proper surgical management. Roentgenograms and bronchograms when properly employed are perhaps our best means of identifying intrapulmonary lesions. When these are combined with bronchoscopic observation and biopsy, pneumothorax and bronchial secretion examination

the true nature of the lesion may be found in a high percentage of cases. The difficulties of diagnosis in the early and uncomplicated stage of the lesion have increased in number in recent years with the routine roentgenologic or fluoroscopic examination of the chest of employees of many industrial, educational, and other institutions. At this early stage no symptoms have been experienced and the physical examination reveals no apparent abnormality. The responsibility of deciding at that time as to proper therapy is much greater because frequently all means of diagnosis fail to determine the nature of the lesion. Further, it is at this early date that proper therapy should be instituted since in the case of malignancy the prognosis for a long time cure is quite good. All too frequently however the lesion is viewed as insignificant since it has given rise to no symptoms. The physician, as well as the patient, is given a false sense of security by the fact that symptoms and altered physical findings are absent.

What are some of the more common lesions which present this problem of diagnosis and early therapeutics? One of the more common conditions in which a delay in diagnosis is of prime importance is primary carcinoma of the lung. Approximately from 25 per cent to 35 per cent of these lesions arise in the periphery of the lung, away from the main bronchi. At an early stage they appear as a circumscribed opacity and produce no symptoms. Their rate of growth is variable but many may be present for a number of months or even years before their presence is manifested. When found on fluoroscopic or x ray examination these lesions are frequently mistaken for tuberculosis. This error is made especially because of the slow rate of growth of the lesion and the appearance at times of small cavities within the opaque area. In spite of the fact that the sputum if present, remains negative

for tubercle bacilli the diagnosis of tuberculosis may be entertained for a long period of time.

Peripheral tumors frequently undergo central necrosis with cavity formation. Infection follows and leads to the production of signs and symptoms of a lung abscess. At one time it was thought that these peripheral lesions carried a poor prognosis. This conclusion was based on the fact that the lesion was far advanced when symptoms first developed and the condition was first recognized. It is now known that, if the tumor can be identified before symptoms have been produced, the prognosis for a long time cure following extirpation is very good. When it is appreciated that almost one-third of primary lung cancers arise in the peripheral region, the importance of early exploration after a reasonable period of study to rule out other conditions will improve the outlook for this lesion in a high percentage of cases. It has been our experience at the University of Chicago Clinics that the peripheral group of primary lung cancer when diagnosed and explored at an early date has a much better chance for a long time cure than have those tumors arising in the main stem bronchi. Examination of the bronchial secretions will give positive results in some cases. The lack of facilities for using this method of diagnosis should never delay the prompt institution of proper surgical therapy. Since exploratory thoracotomy in itself carries very little risk, these patients should receive its benefit rather than have proper treatment delayed until a chance for cure is past.

In other patients primary lung tumors are frequently diagnosed as unresolved pneumonia, virus pneumonia or pneumonitis. This mistaken diagnosis is particularly apt to be made when the lesion is in the upper lobe and therefore cannot be visualized through a bronchoscope. A study of the bronchial se-

cretions may be indeterminate. If there is no specific evidence to support the diagnosis of unresolved pneumonia or pneumonitis the likelihood of malignancy should be strongly considered and investigated without delay. At the present time through the use of chemotherapeutics, most pyogenic infections of the lung will respond in a reasonable length of time. Since the risk of lung resection has been reduced to a very reasonable level this form of treatment should be considered if the diagnosis cannot be otherwise ascertained. The incidence of carcinoma of the lung is so much greater than that of chronic pneumonitis or unresolved pneumonia that the chance of resecting a nonmalignant lesion is unlikely.

During recent years a congenital abnormality of the lung i.e. cystic malformation has been more frequently recognized. This condition produces symptoms usually after the involved region has become infected. The clinical picture at times is not unlike that of lung abscess, tuberculosis or primary lung tumor. In most cases differentiation is possible. However at times since the lung becomes airless x ray examination and other means of diagnosis fail to reveal the true nature of the condition. When these patients are properly prepared for operation by the use of chemotherapeutic agents blood transfusion and other replacement therapy exploration is attended with little risk and the lesion can be dealt with in a satisfactory manner.

Mediastinal tumors, chronic inflammations and congenital cysts are sometimes difficult to recognize or to differentiate from lesions arising in the lung. Many of these lesions remain entirely asymptomatic until through pressure on adjacent structures a pulmonary infection is produced or there is interference with the function of the adjacent organs. The clinical features and x ray findings are virtually the only means on which to base a

working diagnosis. If the lesion can be dealt with before complications arise the problem of satisfactory treatment is not nearly so great and the morbidity is considerably reduced. Mediastinal dermoids bronchogenic cysts, and congenital abnormalities of the vessels of the mediastinum fall into this group. Mediastinal dermoids are prone to undergo malignant degeneration and thus present an additional indication for exploration and removal at a time when they may seem innocuous due to the fact that no symptoms have been produced.

Much progress has been made in the operative care of intrapulmonary lesions. If the benefit of early exploration in patients with indeterminate lesions is kept in mind the outlook for pulmonary malignancy will be much improved.

W. E. ADAMS.

PRESENT STATUS OF PULMONARY DECORTICATION

THE present interest in pulmonary decortication is an outgrowth of experience acquired during World War II. Military surgeons when faced with the problem presented by massive clotted and organizing pleural accumulations under which lungs were collapsed accepted the challenge by opening the thorax removing the pleural content and stripping from the visceral pleura the confining envelope of organized fibrin.

As experience accumulated there evolved the concept of a lung retained in a state of collapse by peripleural fibrous or fibrinous investments independent of any gross intrapleural mass. The operative procedure itself was amplified to include not only the removal of restraining pleural peels but also a complete mobilization of the lung so that it could lie free within the thorax and be unhampered in expansion. Thus, it was capable of completely filling its hemithorax in a very brief period of time.

This present day concept of decortication contrasts with the operative procedure carried out by Delorme, Ransohoff, and others. These pioneers, working in an infected field and without the protection of modern adjuncts to surgery, were forced to keep their dissections from violating uncontaminated pleural recesses. When confronted with persistent intrapleural spaces, therefore, they carried the chest wall to meet the collapsed lung but by thinning or removing the thick visceral peel they utilized what expansibility of lung they could muster in order to lessen the final gap between the lung and chest wall. Whereas these men resorted to decortication late in the course of disease, the modern approach calls for relatively early exhibition of the procedure.

The basic indication for pulmonary decortication lies in a lung that cannot re-expand because it is held in the collapsed position by peripleural investments. Each of the following factors must be considered: (1) the bronchial tree must be patent so that air can enter the lung freely, (2) the lung itself must be intrinsically capable of expansion, (3) the content of the pleura must be displaceable or removable in order to demonstrate that its mere presence is not maintaining collapse, and finally (4) there must have existed a pleural process capable of laying down a restraining peripulmonary deposit.

To determine patency of the air passages bronchoscopy is required. Thoracentesis can generally demonstrate the nature of the pleural content as well as its displaceability. The inherent ability of the lung to expand can only be appraised by clinical evaluation which needless to say may involve extensive investigation. Any lung which fails to expand after removal or effective neutralization of its pleural factor must be considered as captive on a mechanical basis if its bronchial tree is patent and its intrinsic expansibility is assured.

Considering in more detail the pleural factors it should be recalled that inaspirable (solid or semisolid) pleural accumulations are usually fibrinous in nature and maintain collapse by their bulky presence, and that the mere removal of this pleural mass is not likely to suffice in promoting pulmonary re-expansion because a perivisceral envelope of organized fibrin is probably present if the process is a week or more old. In the presence of a bronchopleural fistula adequate neutralization of the pleural factor (air) may not be possible because it is being constantly replaced. Likewise any pleural process which produces fluid continuously must be looked upon with suspicion because a true retaining cicatricial peel is not capable of significant secretory or transudative activity. Although continued production of pleural fluid can occur concomitantly with the deposition of a retaining peel, it is not likely that under these circumstances the mechanical retention of the lung in the collapsed state will be an important feature of the clinical problem. Pleural neoplastic implants for example frequently behave in this manner.

In addition to these basic considerations one additional requirement must be satisfied namely that the process responsible for the production of the collapsed and captive lung is controlled or quiescent, or at least that it can be controlled at the time of decortication.

Acute pyogenic empyemas do not generally provide the basic indication for decortication because adequate management of the pleural factor (which must include dependent drainage) usually results in pulmonary re-expansion even though this may occur slowly. The more indolent pleural infections on the other hand such as are occasionally seen in pleurae surgically contaminated by staphylococci may require aggressive treatment because of copious production of heavy fibrinous pleural

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

THE Swiss obstetricians and gynecologists recently decided to prepare textbooks of obstetrics and gynecology themselves instead of depending upon German and French textbooks. Guggenberger and his associates wrote the textbook of gynecology and the two volumes which constitute the textbook of obstetrics were prepared by Koller with the assistance of nine other Swiss obstetricians who teach and practice in Basel, Zurich and Geneva. The book was written in German. There will be a third book devoted to operative obstetrics.

There are 1,323 pages in the two volumes and 711 illustrations. Of the 1,261 pages of text (the remaining 62 pages are devoted to the index) 180 pages or exactly one-seventh of both volumes are given over to fetal monstrosities (100 pages) and pathology of the newborn (80 pages). Likewise, 143 of the 711 illustrations or one fifth of all the illustrations, pertain to abnormalities of the newborn. The amount of space devoted to the newborn (aside from the chapter on the physiology of the newborn) seems disproportionately great. Many illustrations have been borrowed or copied from other textbooks but all of them are excellent.

The authors describe and illustrate methods of resuscitating newborn babies including Schultze's swappings. These procedures are dangerous and should not be used. Likewise there is a detailed description and two illustrations of the Credé method of expressing the placenta, but this manipulation can do great harm and should be forgotten. We have far safer ways of expressing the placenta.

As in the United States the author (Held) agrees that in cases of pre-eclampsia if improvement does not follow conservative treatment, the uterus should be emptied by induction of labor from below or by cesarean section. However in cases of eclampsia three forms of therapy are described namely active conservative, and "middle line." Koller prefers the "middle line" treatment of eclampsia and advises against cesarean section. Most obstetricians in the United States also favor conservatism for nearly all cases of eclampsia.

In cases of placenta previa, chief reliance is placed upon the transperitoneal cervical cesarean section for the serious cases and rupture of the membranes for the mild cases. The author (Koller) properly cautions against forcible dilatation of the cervix in cases of placenta previa.

The ten authors of this book are to be congratulated on having written an excellent textbook. Naturally the style is not uniform, but all the authors have presented their subjects in simple lucid language. The advice given is nearly always conservative and in accordance with the practice of leading obstetricians everywhere in the world. The illustrations are well chosen, abundant and highly instructive. The publishers also are to be commended for the paper is good, the type is clear and the illustrations have been clearly reproduced. This textbook will undoubtedly be very popular not only in Switzerland, but also in other parts of the world where physicians and students read German.

J. F. GREENHILL.

THE authors of *Nouvelles techniques de traitement des fractures* give a fairly complete review of recent developments in fracture treatment by the use of open and closed methods. The principal theme is their use of Kirschner wires to secure fragments by transverse or intramedullary fixation. They describe their animal experiments to show that Kirschner wire fixation causes little interference with bone healing. They also depict a reducing frame which permits the use of traction in any direction, as well as a number of special wire guides which they have devised.

A preface by their teacher, Prof. J. Leveuf of the University of Paris, states that the authors are the originators of the method of Kirschner wire fixation "with the minimum of surgery." This is in keeping with the ideals of their common mentor, Pierre Delbet, who constantly strove for preservation of function while securing union of the fractures.

Each type of fracture in the body is considered and the latest developments in treatment are described. Some old material is used, such as the various reconstruction operations of the hip and the different types of bone grafts. On the other hand much attention is paid to the newer methods of intramedullary pin fixation of fractures.

The book is well planned and the illustrations are good but there are very few bibliographic references to correspond to the names mentioned in the text. While this is a fault it can be excused as they say it was published in a difficult period when library facilities were far from adequate.

WALTER G. STUCK.

LEHRBUCH DER GEBURTSHILFE. Vols. 1 and 2. By Th. Koller. Basel, Switzerland. S. Karger 1942.

NOUVELLES TECHNIQUES DE TRAITEMENT DES FRACTURES. By H. Godard and R. Michel-Bebet. Paris. G. Doin & Co. 1942.

THE textbook of physiology *Human Physiology*¹ edited for medical students by two teachers at University College London is an astonishingly complete treatment of the subject in 564 pages of material. Chapters have been contributed by Picken Mackay Gregory, Smyth Young Newton, P Eggleston Whitteridge, Feldberg, Lythgoe, Rawdon Smith and M G Eggleston nevertheless the multiple authorship is less evident than is the case for most compendia as the editors have succeeded admirably in achieving a homogeneity of style. It is probably inevitable that some chapters are superior to others in the extent and clarity of the exposition but there is no segment of the vast field of physiology that is neglected. One of the techniques utilized in achieving comprehensiveness with minimal verbiage is the intrusion of definitions etc. as parenthetical material. The following examples are illustrative: a reduction of the alkali reserve (acidosis) red cells may clump together (agglutinate) micturating

membrane (a third eyelid present in some species). To attain economy of space there is little or no bibliographic material but there is a surprisingly great amount of illustrative material in the form of figures, diagrams and charts. Many of these are excellent but a few (time-worn heritages of earlier texts) could be dispensed with without penalizing the quality of the book.

In general the book is not directed toward being an applied physiology in the sense that it is primarily devoted to the exposition of clinical phenomena but in the opinion of the reviewer this is an asset rather than a liability. Clinical applications (where important) are dealt with but there is no evasion of the material for which as yet, the clinical counter parts are missing. It is a praiseworthy addition to the library of this field.

Ynrk University Post-Graduate Division, and chairman of the Committee on Fractures and Other Traumas of the American College of Surgeons

PRESIDENTIAL MEETING

The opening evening session of the Clinical Congress will be devoted to the Presidential Meeting at which the officers-elect, consisting of Dr Dallas B Phemister of Chicago as president, Dr Howard A Patterson of New York as first vice president and Dr Carl H McCaskey of Indianapolis as second vice president will be installed. Dr Arthur W Allen of Boston outgoing president and vice-chairman of the Board of Regents will preside and will deliver the Presidential Address on the subject "Looking Forward." The third Martin Memorial Lecture will be delivered by Dr Clarence Crafoord professor of surgery, University of Stockholm. Dr Crafoord's subject will be "Some Aspects of the Development of Intrathoracic Surgery."

CONVOCATION

The Annual Convocation will be held on the final evening Friday. The formal induction ceremonies and the presentation of the Fellowship Address by Dr George W Beadle Professor of Biology and chairman Department of Biology, California Institute of Technology Pasadena, will constitute the program. Dr Beadle's subject will be, "Hereditary Errors in Metabolism."

ASSEMBLY OF INITIATES

The 1948 initiates will attend an assembly on Friday afternoon from 1:30 to 2:15 o'clock in the Temple Baptist Church. Dr Dallas B Phemister incoming president of the College, will preside. Dr Irvin Abell chairman of the Board of Regents and Dr Malcolm T MacEachern Dr H Prather Saunders and Dr Charles F Branch will briefly outline the program of the College.

OTHER OFFICIAL MEETINGS

The annual meeting of the Governors and Fellows of the College will be held on Thursday afternoon at 1:30 o'clock. Reports on activities of the American College of Surgeons will be presented by the officers and chairmen of the standing committees, followed by the election of officers.

Meetings of three important committees will be held on Wednesday as follows: State and Provincial Executive Committees, 9:00 to 10:00 a.m.; State and Provincial Credentials Committees and Committees on Applicants and Judiciary Committees, 10:00 to 11:00 a.m.; and National and

Regional Fracture Committees, 3:30 to 5:00 p.m. The Committee on the Library will meet on Thursday from 3:00 to 4:00 p.m. A dinner for the members of the Committee on Fractures and Other Traumas, and for the chairmen of the Regional Committees will be held from 6:00 to 8:00 p.m. on Thursday.

FORUM ON FUNDAMENTAL SURGICAL PROBLEMS

The Forum on Fundamental Surgical Problems one of the most popular features of Clinical Congresses during the past few years will be held on Tuesday through Friday mornings, in two sections meeting concurrently. Brief reports of original clinical and experimental observations relating to the broad aspects of surgery and the surgical specialties will be presented, under the general direction of Dr Owen H Wangensteen chairman of the committee, Forum on Fundamental Surgical Problems.

GENERAL SURGERY

In general surgery the program at the headquarters hotel will embrace three evening symposia and seven afternoon panel discussions.

On Thursday afternoon there will be only one panel discussion from 3:30 to 5:00.

Detailed programs are published on succeeding pages.

SURGICAL SPECIALTIES

Panel discussions on the surgical specialties will be held on Friday afternoon from 1:30 to 4:45 o'clock. The panels will be held concurrently in the following fields: urology, orthopedic surgery, neurologic surgery, gynecology and obstetrics, thoracic surgery and plastic surgery. Programs are shown on succeeding pages.

OPHTHALMOLOGY

The program for ophthalmologists will consist of two evening sessions, three morning panel discussions from 9:00 to 10:30 and an evening session on Wednesday in which a combined program with the otorhinolaryngologists will be held.

OTORHINOLARYNGOLOGY

The program in otorhinolaryngology will consist of two evening meetings, an evening session on Wednesday in which a combined program with the ophthalmologists will be held and three morning panel discussions from 10:45 to 12:15. The fact that the morning panel discussions are planned to follow those on ophthalmology will enable surgeons who combine these specialties in their practice to attend both sessions.

SYMPOSIUM ON CANCER

On Tuesday afternoon from 2:00 to 5:00 a Symposium on Cancer Is Curable will be held at which surgeons will report on series of cancer survivals, without recurrence, of from five to twenty five years, and the College will report the additions to its Archives of Cancer Cures.

On Wednesday afternoon from 2:00 until 5:00 o'clock a Symposium on Cancer with Dr Grantley W Taylor of Boston, chairman of the Cancer Committee American College of Surgeons, presiding is scheduled. The list of subjects together with the speakers is published on another page.

SYMPOSIUM ON FRACTURES AND OTHER TRAUMAS

Dr Robert H Kennedy of New York, chairman, Committee on Fractures and Other Traumas, will preside at the Symposium on Fractures and Other Traumas which will be held on Tuesday from 2:00 to 5:00 p.m. The speakers are listed in the outline of the program which appears on succeeding pages.

SYMPOSIUM ON GRADUATE TRAINING IN SURGERY AND THE SURGICAL SPECIALTIES

Dr Frederick A Collier of Ann Arbor, chairman, Committee on Graduate Training in Surgery of the College will preside at the Symposium on Graduate Training in Surgery and the Surgical Specialties which will be held on Thursday afternoon from 3:00 to 5:00 o'clock.

HOSPITAL STANDARDIZATION CONFERENCE

The first formal session of the Clinical Congress will be the opening meeting of the twenty-seventh Hospital Standardization Conference at 10:00 o'clock on Monday morning October 18. The plans for this meeting are described on a preceding page under the heading General Assembly and the preliminary outline of the program is included in a later section.

The hospital conferences will continue on Monday afternoon, with sessions following on Tuesday Wednesday and Thursday mornings, after noons, and evenings, and all day Friday when visits will be arranged to hospitals in Los Angeles and vicinity with the cooperation of the Southern California Hospital Council, to study special features and observe procedures in general.

Hospital administrators, members of governing boards, medical staff members, heads of the various hospital departments and their personnel, nurses, dietitians, medical records librarians, and many other persons directly concerned about hospital progress, will be interested in the timely discussions of a wide range of hospital problems.

Aiding with the program are the following members of the Hospital Standardization Conference committee: Ritz E. Heerman, superintendent, The California Hospital; chairman Paul C. Elliott, superintendent Hollywood Presbyterian Hospital; and President, Southern California Hospital Council and Alden B. Mills, administrator Huntington Memorial Hospital, Pasadena.

A joint session with the American Association of Medical Record Librarians will be held on Wednesday afternoon. A forum on fundamental administrative problems, with administrative interns and graduates of the schools of hospital administration as the participants will be held on Thursday afternoon.

The evening meetings will be as follows: Tuesday evening a round table conference on Hospital Standardization and the Point Rating System; Wednesday evening a forum for hospital trustees and administrators; Thursday evening a panel discussion on "Nursing the Patient" with the subject presented from various points of view.

COMMITTEE ON ARRANGEMENTS

A list of the members of the Committee on Arrangements for the Clinical Congress in Los Angeles follows:

General Committee

Donald G. Tollefson, M.D. F.A.C.S., *Chairman*
Hugh T. Jones, M.D. F.A.C.S., *Vice Chairman*
Harold Lincoln Thompson, M.D. F.A.C.S. *Secretary-Treasurer*
Gilbert J. Thomas, M.D. F.A.C.S. *Represent of the College*
F. Vincent Askey, M.D. F.A.C.S.
Max W. Bay, M.D. F.A.C.S.
J. MacKenzie Brown, M.D. F.A.C.S.
Lawrence Challen, M.D. F.A.C.S.
A. Ray Irvine, M.D. F.A.C.S.
Maurice Kahn, M.D. F.A.C.S.
W. E. MacPherson, M.D.
B. O. Ransford, M.D.
Louis J. Regan, M.D.
Carl Kuebe, M.D., F.A.C.S.
Stanford W. Wren, M.D.

Committee for the Southern California Chapter

Ray B. McCarty, M.D. F.A.C.S., Riverside
Meredith G. Benzer, M.D. F.A.C.S., Redlands
Clarence E. Rees, M.D. F.A.C.S., San Diego
Carl G. Johnson, M.D. F.A.C.S., Long Beach
James H. Saint, M.D. F.A.C.S., Santa Barbara

Hospital Committee

The members of the hospital committee are listed on succeeding pages with the list of hospitals participating in the clinical program.

MEDICAL MOTION PICTURES

An appreciated feature of the Clinical Congress will again be the showing of medical motion pictures.

es each day. The latest available pictures on surgery and related subjects will be presented. Special showings will be arranged of medical motion pictures in the fields of ophthalmology and otolaryngology. Both sound and silent films will be shown all of which will have been approved by the Committee on Motion Pictures. Some of the newer medical motion pictures now under production will be shown.

TECHNICAL AND SCIENTIFIC EXHIBITIONS

The Technical and Scientific Exhibits will occupy the Ballroom foyer, the Renaissance Room and the Galleria of the Biltmore Hotel according to present plans. Leading manufacturers of surgical instruments, x ray apparatus, sterilizers, operating room lights, ligatures, dressings, hospital apparatus, supplies, and pharmaceuticals and publishers of medical books will be represented.

ENTERTAINMENT FOR LADIES AND GUESTS

The Committee on Arrangements is planning a most interesting program for the wives and other guests of Fellows who are attending the Clinical Congress. Among the events planned are motor tours in and around Los Angeles to include such attractions as the Huntington Library, Griffith Park Planetarium, Olvera Street, Chinatown, visits to Hollywood studios and homes of motion picture stars and radio broadcasts. Tickets to the broadcasts will be available upon request only at the registration desk at the Biltmore Hotel.

There will be a separate charge for each of the entertainment events. Each Fellow who registers in advance will receive a card listing the entertain-

ment activities which he must check if he is interested and return the card accompanied by personal check to cover the total amount to Mrs. Verne C. Hunt, Box 95, San Marino, California.

ADVANCE REGISTRATION

Surgeons who wish to attend the Congress should register in advance. Under a new plan advance registration will greatly expedite the procedure of registering.

No registration fee will be charged. Fellows whose dues are paid to December 31, 1947, for endorsed Juniors and Senior Candidates, the fee will be \$5.00. Non-Fellows who after individual consideration are permitted to register, will pay a fee of \$10.00.

No registration fee will be required of initiates of the class of 1948.

HOTEL RESERVATIONS

It is desirable to make hotel reservations as early as possible because of the shortage of hotel rooms that prevails in Los Angeles as well as in other cities. In making these communications should be addressed to the Los Angeles Convention and Visitors Bureau care of the Los Angeles Chamber of Commerce, stating that you will be attending the Clinical Congress of the American College of Surgeons. All hotel reservations for the Clinical Congress are to clear through this Bureau. No correspondence should be sent directly to the hotels. A form for reservations was enclosed in the letter recently sent to Fellows. Choice of hotels may be designated. The hotels in Los Angeles require a deposit in advance.

CLINICAL CONGRESS PROGRAM IN BRIEF

Monday, October 18

- 8:00-12:00 Clinics and Demonstrations—Local Hospitals
- 9:00-12:30 General Assembly—Ballroom
- 1:30-3:00 Panel Discussion—Philharmonic Auditorium
- 3:00-4:00 Television Surgical Specialties—Foyer Biltmore Bowl (Lower Level)
- 4:00-5:00 Clinics and Demonstrations—Local Hospitals
- 5:00-6:00 Hospital Conference—Ballroom
- 6:00-7:00 Panel Discussion—Philharmonic Auditorium
- 7:30-8:00 Presidential Meeting—Philharmonic Auditorium
- 8:15-10:30 Presidential Meeting—Philharmonic Auditorium

Tuesday, October 19

- 8:00-1:00 Clinics and Demonstrations—Local Hospital
- 8:30-12:00 Forum on Fundamental Surgical Problems—Philharmonic Auditorium
- 8:10-12:00 Forum on Fundamental Surgical Problems—Ballroom
- 9:00-10:30 Panel Discussion Ophthalmology—Conference Room No. 1

- 9:30-12:30 Surgical Film Exhibition (General)—Biltmore Theater
- 10:00-12:30 Hospital Conference—Music Room
- 10:00-12:00 Television General Surgery—Foyer Biltmore Bowl
- 10:45-12:15 Panel Discussion—Otolaryngology—Conference Room No. 1
- 1:30-3:00 Panel Discussion—Philharmonic Auditorium
- 3:00-5:00 Clinics and Demonstrations—Local Hospitals
- 2:00-4:00 Television Surgical Specialties—Foyer Biltmore Bowl
- 2:00-4:00 Surgical Film Exhibition (E.E.N.T.)—Conference Room No. 1
- 2:00-5:00 Hospital Standardization Conference—Music Room
- 2:00-5:00 Symposium Cancer Is Curable—Ballroom
- 2:00-5:00 Symposium on Fractures and other Traumas—Biltmore Theater
- 3:30-5:00 Panel Discussion—Philharmonic Auditorium

- 7:00-8:00 Surgical Film Exhibition (E.E.N.T.)—Conference Room No. 6
 8:00-9:00 Hospital Conference—Music Room
 8:00-9:00 Scientific Session—General Surgery—Philharmonic Auditorium
 8:00-9:00 Scientific Session—Ophthalmology—Conference Room No. 6
 8:00-9:00 Scientific Session—Otorhinolaryngology—Conference Room No. 6

Wednesday, October 20

- 7:45-9:45 Breakfast Conference—Press and Radio Representatives and Hospital Personnel—Conference Room No. 6
 8:00-9:00 Meeting of Cancer Committee—Conference Room No. 6
 8:00-9:00 Clinics and Demonstrations—Local Hospitals
 8:30-9:00 Forum on Fundamental Surgical Problems—Ballroom
 8:30-9:00 Forum on Fundamental Surgical Problems—Philharmonic Auditorium
 9:00-9:00 Panel Discussion—Ophthalmology—Conference Room No. 6
 9:00-9:00 State and Provincial Executive Committees—West Gold Room, Ambassador Hotel
 9:30-9:00 Surgical Film Exhibition (General)—Biltmore Theater
 9:00-9:00 Hospital Conference—Music Room
 9:00-9:00 Television, General Surgery—Foyer Biltmore Bowl (Lower Level)
 9:00-9:00 State and Provincial Credentials Committees and Committees on Applicants and Judicial Committees—West Gold Room, Ambassador Hotel
 9:45-9:00 Panel Discussion—Otorhinolaryngology—Conference Room No. 6
 9:00-9:00 Luncheon—Meeting of Board of Governors—West Gold Room, Ambassador Hotel
 9:30-9:00 Panel Discussion—Philharmonic Auditorium
 9:30-9:00 Clinics and Demonstrations—Local Hospitals
 9:00-9:00 Surgical Film Exhibition (E.E.N.T.)—Conference Room No. 6
 9:00-9:00 Television, Surgical Specialties—Foyer Biltmore Bowl (Lower Level)
 9:00-9:00 Symposium on Cancer—Ballroom
 9:00-9:00 Hospital Conference—Music Room
 9:30-9:00 Panel Discussion—Philharmonic Auditorium
 9:30-9:00 Meeting of National and Regional Fracture Committees—Conference Room No. 6
 7:00-8:00 Surgical Film Exhibition (E.E.N.T.)—Conference Room No. 6
 8:00-9:00 Combined Session—Ophthalmology and Otorhinolaryngology—Conference Room No. 6
 8:00-9:00 Scientific Session, General Surgery—Philharmonic Auditorium
 8:00-9:00 Hospital Conference—Music Room

Thursday, October 21

- 8:00-9:00 Clinics and Demonstrations—Local Hospitals
 8:30-9:00 Forum on Fundamental Surgical Problems—Ballroom
 8:30-9:00 Forum on Fundamental Surgical Problems—Philharmonic Auditorium
 9:00-9:00 Panel Discussion, Ophthalmology—Conference Room No. 6

- 9:00-12:00 Surgical Film Exhibition (General)—Biltmore Theater
 9:00-9:00 Hospital Conference—Music Room
 9:00-9:00 Television, General Surgery—Foyer Biltmore Bowl
 9:45-9:00 Panel Discussion, Otorhinolaryngology—Conference Room No. 6
 9:30-9:00 Adjourned Meeting, Governors—Ballroom
 9:45-9:00 Annual Meeting, Foyer Biltmore Bowl
 9:00-9:00 Television, Surgical Specialties—Foyer Biltmore Bowl
 9:00-9:00 Clinics and Demonstrations—Local Hospitals
 9:00-9:00 Hospital Conference—Music Room
 9:00-9:00 Surgical Film Exhibition (General)—Biltmore Theater
 9:00-9:00 Committee on The Library—Conference Room No. 6
 9:00-9:00 Symposium, Graduate Training in Surgery—Ballroom
 9:30-9:00 Panel Discussion—Philharmonic Auditorium
 9:00-9:00 Dinner for Committee on Fractures and Other Traumas and Chairmen, Regional Committees—Engineers' Club
 7:00-8:00 Surgical Film Exhibition (E.E.N.T.)—Conference Room No. 6
 8:00-9:00 Hospital Conference—Music Room
 8:00-9:00 Scientific Session—General Surgery—Philharmonic Auditorium
 8:00-9:00 Scientific Session—Ophthalmology—Conference Room No. 6
 8:00-9:00 Scientific Session—Otorhinolaryngology—Conference Room No. 6

Friday, October 22

- 8:00-9:00 Clinics and Demonstrations—Local Hospitals
 8:30-9:00 Forum on Fundamental Surgical Problems—Ballroom
 8:30-9:00 Forum on Fundamental Surgical Problems—Philharmonic Auditorium
 9:30-9:00 Surgical Film Exhibition (E.E.N.T.)—Biltmore Theater
 9:30-9:00 Hospital Conference—Visits to Hospitals
 9:00-9:00 Television, General Surgery—Foyer Biltmore Bowl
 9:00-9:00 Surgical Film Exhibition (General)—Biltmore Theater
 9:00-9:00 Assembly of Initiates—Temple Baptist Church
 9:30-9:00 Hospital Conference—Ballroom
 9:45-9:00 Panel Discussions for each of the following: Gynecology and Obstetrics—Conference Room No. 6
 Plastic Surgery—Conference Room No. 6
 Neurological Surgery—Ballroom
 Thoracic Surgery—Burdett Hall, Temple Baptist Church
 Urology—Auditorium, Southern California Edison Building
 Orthopedic Surgery—Biltmore Theater
 9:00-9:00 Television, Surgical Specialties—Foyer Biltmore Bowl
 9:00-9:00 Clinics and Demonstrations—Local Hospitals
 7:30-8:00 Assembly of Initiates for Processional—Temple Baptist Church
 8:30-9:00 Convocation—Philharmonic Auditorium

GENERAL ASSEMBLY

JOINT SESSION—SURGEONS AND HOSPITAL REPRESENTATIVES

Monday 10 00 a m —12 30 p m.—Ballroom—Biltmore Hotel

- ARTHUR W ALLEN M.D. F.A.C.S., Boston President, American College of Surgeons Presiding
Address of Welcome from the City of Los Angeles HONORABLE FLETCHER BOWRON Los Angeles Mayor of
City of Los Angeles
Greetings from the Association of Western Hospitals HORACE TURNER, Spokane President
Looking Forward With Hospital Standardization ARTHUR W ALLEN M.D., Boston
Activities of the American College of Surgeons—A Dynamic Program IRVIN ABELL, M.D. F.A.C.S.
Louisville Chairman Board of Regents.
Preservation of the Voluntary Hospital System REV JOHN J FLANAGAN S.J. St Louis Executive Direc
tor Catholic Hospital Association.
The Hospital of Tomorrow JAMES A. HAMILTON Minneapolis Professor and Director Course in Hospital
Administration University of Minnesota Hospital Consultant
The Value of Motion Pictures in Medical Education CHARLES B PUESTOW M.D. M.Sc. Ph.D. F.A.C.S.
Chicago Professor of Surgery and Assistant Dean in Charge of Education in Surgery University of
Illinois College of Medicine and Illinois Post Graduate Medical School Chief Surgical Consultant
Veterans Administration Hospital Hines Chairman Committee on Medical Motion Pictures American
College of Surgeons.
Premiere Showing An Introduction to FRACTURES Film Directed by Harrison L. McLaughlin M.D.
New York Assistant Professor of Clinical Orthopedic Surgery Columbia University College of Physi
cians and Surgeons.
(Sponsored by the American College of Surgeons and Committee on Fractures and Other Traumas and
made possible through a grant from the Johnson & Johnson Research Foundation)
Introduced by ROBERT H KENNEDY M.D. F.A.C.S. New York Clinical Professor of Surgery
New York University College of Medicine Post Graduate Division Chairman Committee on Frac
tures and Other Trauma, American College of Surgeons

EVENING SCIENTIFIC SESSIONS

GENERAL SURGERY

Tuesday 8 00-10.30 p m

Symposium on Malignant Lesions of the Thyroid Gland

- Histologic Types of Thyroid Carcinoma and Their Clinical Significance FRANK W FOOTZ M.D. New York
Aberrant Thyroid BRIEN T KING, M.D. F.A.C.S. Seattle
Malignancy in Nodular Goiter WARREN H. COLE, M.D. F.A.C.S. Chicago
Radioactive Iodine for the Treatment of Thyroid Disease Including Carcinoma. MYRON PRINZMETAL
M.D. Los Angeles

Wednesday 8 00-10 30 p m

- Fracture Oration Colles Fracture HENRY C. MARBLE M.D. F.A.C.S. Boston

Symposium on Endometriosis

- Etiology of Endometriosis BROOKS RANNEY M.D. Chicago
Surgical Procedures Involved in the Treatment of Endometriosis VIRGIL S. COUNSELLER M.D. F.A.C.S.
Rochester Minnesota.
The Medical Treatment and Significance of Endometriosis. JOE V. MEIGS M.D. F.A.C.S. Boston

Thursday 8 00-10.30 p m

Symposium on Surgery of the Heart and Great Vessels

- Surgical Treatment of Pulmonic Stenosis. ALFRED BLALOCK M.D. F.A.C.S. Baltimore
The Surgical Treatment of Constrictive Pericarditis EMILE F. HOLMAN M.D. F.A.C.S. San Francisco
The Surgery of Patent Ductus Arteriosus. JOHN C. JONES, M.D. F.A.C.S. Los Angeles.
Treatment of Coarctation of the Aorta ROBERT E. CROSS M.D. F.A.C.S. Boston

OPHTHALMOLOGY

Tuesday 8:00-10:30 p.m.

Tumors of the Eyelids and the Conjunctiva. MICHAEL J. HOGAN, M.D., San Francisco.
 Partial Keratectomy. GEORGE L. KILGORE, M.D., San Francisco.
 Diathermy Cauterization of the Ciliary Body for Glaucoma. SAMUEL J. MEYER, M.D., F.A.C.S., Chicago.

Thursday 8:00-10:30 p.m.

The Use of Retrobulbar Alcohol Injection for Ocular Pain. ALFRED E. MAUMENSTEIN, M.D., Baltimore.
 The Differential Diagnoses of Retinal Detachment and its Operative Treatment. DOUGLASS K. PUGH, M.D., San Francisco.
 Correlation of the Anatomical Factors Concerned in the Ophthalmoscopic Appearance of Retinal Hemorrhages. HOMER F. SMITH, M.D., Salt Lake City.

OTORHINOLARYNGOLOGY

Tuesday 8:00-10:30 p.m.

Effect of Streptomycin on Eighth Nerve Function. PAGE NORTHINGTON, M.D., F.A.C.S., Oakland.
 Anatomical Considerations in Ear Surgery. J. BROWN FARRIOR, M.D., F.A.C.S., Tampa.
 Chronic Laryngeal Stenosis. JOHN B. ERICH, M.D., F.A.C.S., Rochester, Minnesota.

Thursday 8:00-10:30 p.m.

Present Day Status of Frenotomy Surgery. LEIGHTON F. JOHNSON, M.D., F.A.C.S., Boston.
 Tumors of the Nasopharynx. HARRY C. ROSENBERGER, M.D., F.A.C.S., Cleveland.
 The Modern Management of Oro-Antral Fistula. RICHARD THOMAS BARTON, M.D., Beverly Hills.
 Surgical Treatment of Laryngeal Cancer. CHEVALIER L. JACKSON, M.D., F.A.C.S., Philadelphia.

COMBINED SESSION—OPHTHALMOLOGY—OTORHINOLARYNGOLOGY

PANEL DISCUSSION

Wednesday 8:00-10:30 p.m.

Neoplasms of the Eyelids, Orbit, Nose and Accessory Sinuses: Treatment and Plastic Repair.
 Moderator: GORDON B. NEW, M.D., F.A.C.S., Rochester, Minnesota.
 Collaborators: AUBREY G. RAWLINS, M.D., San Francisco; EDMUND B. SPARTIL, M.D., F.A.C.S., Philadelphia; JOHN B. ERICH, M.D., F.A.C.S., Rochester, Minnesota; MICHAEL J. HOGAN, M.D., San Francisco.

PANEL DISCUSSIONS

GENERAL SURGERY

Monday 1:30-3:00 p.m.

Acute Renal Failure in Surgical Patients.
 Moderator: FREDERICK A. COLLIER, M.D., F.A.C.S., Ann Arbor.
 Collaborators: CHARLES D. CREEVEY, M.D., Minneapolis; ERNEST E. MUTHHEAD, M.D., Dallas; WILLIAM O. RUSSELL, M.D., Santa Barbara.

Monday 3:30-5:00 p.m.

Tumors of the Mouth, Jaw and Face.
 Moderator: GORDON B. NEW, M.D., F.A.C.S., Rochester, Minnesota.
 Collaborators: LOUIS T. BLAIR, M.D., F.A.C.S., St. Louis; J. ELLIOTT SCARBOROUGH, JR., M.D., F.A.C.S., Atlanta; ERNEST M. DALAND, M.D., F.A.C.S., Boston.

Tuesday 1:30-3:00 p.m.

Low Living Maligant Lesions of the Bowel.
 Moderator: FRED W. RANKIN, M.D., F.A.C.S., Lexington.
 Collaborators: R. KENNEDY GILCHRIST, M.D., F.A.C.S., Chicago; THOMAS E. JONES, M.D., F.A.C.S., Cleveland; JESSIE GRAY, M.D., Toronto.

Tuesday 3 30-5 00 p m.

Evaluation of Liver Function in Relation to Surgery

Moderator NATHAN A WOMACK M.D. F.A.C.S. Iowa City

Collaborators EVERETT L EVANS M.D. F.A.C.S. Richmond ARTHUR H. BLAKENORE, M.D. New York
JESSE L. BOLLMAN M.D., Rochester Minnesota

Wednesday 1 30-3.00 p m

Peripheral Arterial Disease

Moderator ALTON OCHSNER M.D. F.A.C.S. New Orleans.

Collaborators NORMAN E FREEMAN M.D. F.A.C.S. San Francisco I RIDGEWAY TRIMBLE, M.D.
Baltimore ROBERT R. LINTON M.D. F.A.C.S. Boston

Wednesday 3.30-5 00 p m.

Ulcerative Colitis

Moderator HENRY W CAVE, M.D. F.A.C.S. New York.

Collaborators ALBERT J SULLIVAN M.D. New Orleans CLARENCE DENNIS, M.D. Minneapolis
CLAUDE F DIXON M.D. F.A.C.S. Rochester Minnesota.

Thursday 3.30-5 00 p m

Isotopes in Surgery

Moderator GEORGE M CURTIS M.D. F.A.C.S. Columbus

Collaborators EARL R MILLER, M.D. San Francisco JOSEPH G HAMILTON M.D. Berkeley OLIVER
COPE, M.D. F.A.C.S. Boston BEVERLY C. SMITH M.D. F.A.C.S. New York.

SURGICAL SPECIALTIES, Friday, 1 30-4 55 p m

UROLOGY

Moderator REED M NEBBITT, M.D. F.A.C.S. Ann Arbor

*Present Day Management of Urinary Tract Infections*Collaborators GRAYSON CARROLL, M.D. F.A.C.S. St Louis WILLOUGHBY E KITTREDGE M.D.
F.A.C.S. New Orleans GILBERT J THOMAS M.D. F.A.C.S. Beverly Hills*The Clinical Management of Branched Renal Calculi*Collaborators JAMES T PRIESTLY M.D. F.A.C.S. Rochester Minnesota RUBIN H. FLOCKE, M.D.
F.A.C.S. Iowa City THOMAS E GIBSON M.D. F.A.C.S. San Francisco

ORTHOPEDIC SURGERY

Moderator JOHN C. WILSON M.D. F.A.C.S. Los Angeles

*Mechanical Derangements of the Knee Joint*Collaborators DOUGLAS D TOFFELMIER, M.D. Oakland FRANCIS J COX M.D. San Francisco
FRANCIS E. WEST M.D., San Diego*Fractures About the Hip*Collaborators J SIMS NORMAN M.D. F.A.C.S. Pueblo JOHN J LOUZIENHEISER, M.D. San Fran-
cisco JAMES K. STACK M.D. F.A.C.S. Chicago

NEUROLOGICAL SURGERY

Moderator HOWARD C NAFFZIGER M.D., F.A.C.S. San Francisco

*Cerebral Angiography*Collaborators CARL F LIST M.D. F.A.C.S. Grand Rapids EDWIN B BOLDREY M.D. F.A.C.S.,
San Francisco EARL R. MILLER M.D. San Francisco WALLACE B HAMBY M.D. F.A.C.S.
Buffalo JAMES L. POPPEN M.D. F.A.C.S. Boston

GYNECOLOGY AND OBSTETRICS

Moderator JOHN C BURCH M.D. F.A.C.S. Nashville

*Hysterectomy Physiological Considerations—Indications*Collaborators LANGDON PARSONS M.D. F.A.C.S. Boston CONRAD G COLLINS M.D. F.A.C.S.
New Orleans R. GLENN CRAIG M.D., F.A.C.S. San Francisco KARL H. MARZLOFF M.D.
F.A.C.S. Portland*Hysterectomy Technical Considerations—Complications*

Collaborators (Same as above)

THORACIC SURGERY

Moderator FRANK S. DOLLEY, M.D., F.A.C.S., Los Angeles.

Diagnosis and Surgical Treatment by Pulmonary Resection for Carcinoma, Bronchiectasis and Tuberculosis
 Collaborators EVARTE A. GRAHAM, M.D., F.A.C.S., St. Louis; FRANK B. BERRY, M.D., F.A.C.S., New York; HERBERT C. MAIER, M.D., F.A.C.S., New York.

Surgery of the Esophagus

Collaborators RALPH H. ADAMS, M.D., F.A.C.S., Louisville; LYMAN A. BREWER, III, M.D., F.A.C.S., Los Angeles; JOHN W. STRIEDER, M.D., Boston.

PLASTIC SURGERY

Moderator TRUMAN G. BLOCKER, JR., M.D., F.A.C.S., Galveston.

Congenital Facial Deformities

Collaborators DOUGLAS W. MACOMBER, M.D., F.A.C.S., Denver; WILLIAM S. KISKADDEN, M.D., F.A.C.S., Los Angeles; THOMAS D. CHROMEN, M.D., F.A.C.S., Houston; WALLACE H. STEFFENSEN, M.D., F.A.C.S., Grand Rapids.

Burn Contractures of the Extremities

Collaborators GEORGE V. WEBSTER, M.D., F.A.C.S., Pasadena; GERALD B. O'CONNOR, M.D., F.A.C.S., San Francisco; LOUIS T. BYARS, M.D., F.A.C.S., St. Louis; NATHANIEL B. SOEDERBERG, M.D., F.A.C.S., Phoenixville, Pennsylvania.

OPHTHALMOLOGY

Tuesday 9:00-10:30 a.m.

Surgical Management of Glaucoma

Moderator A. RAY IRVING, M.D., F.A.C.S., Los Angeles.

Collaborators CLAUDE S. MUMMA, M.D., F.A.C.S., Los Angeles; ROBERT N. SHAYFER, M.D., San Francisco; J. HEWITT JUDD, M.D., Omaha.

Wednesday 9:00-10:30 a.m.

Congenital Cataract

Moderator OTTO BARKAN, M.D., San Francisco.

Collaborators S. ROOMAN IRVING, M.D., F.A.C.S., Los Angeles; HAROLD F. WHEALMAN, M.D., Los Angeles; RAYMOND J. NUTTING, M.D., Oakland.

Thursday 9:00-10:30 a.m.

Surgery of the Oblique Muscles

Moderator C. ALLEN DICKEY, M.D., San Francisco.

Collaborators ORWYN H. ELLIS, M.D., F.A.C.S., Los Angeles; AVERY MORLEY HICKS, M.D., San Francisco; ALFRED R. ROBBINS, M.D., Los Angeles.

OTORHINOLARYNGOLOGY

Tuesday 10:45 a.m.-12:15 p.m.

Rehabilitation of the Hard of Hearing

Moderator WALTER P. WORK, M.D., San Francisco.

Collaborators HOWARD P. HOUSE, M.D., F.A.C.S., Los Angeles; S. RICHARD SILVERMAN, M.D., St. Louis; HAROLD M. E. BOYD, M.D., Los Angeles.

Wednesday 10:45 a.m.-12:15 p.m.

The Preparation of the Surgical Patient and Post-Operative Care

Moderator COLBY HALL, M.D., Los Angeles.

Collaborators VICTOR GOODHILL, M.D., F.A.C.S., Los Angeles; CHARLES F. MCCURKEY, M.D., Los Angeles; HAROLD OWENS, M.D., Los Angeles.

Thursday 10:45 a.m.-12:15 p.m.

Diseases of the Esophagus

Moderator ALDEN H. MILLER, M.D., Los Angeles.

Collaborators SIMON JERRERO, M.D., Los Angeles; LEWIS F. MORRISON, M.D., San Francisco; AMBROSE S. CHURCHILL, M.D., Los Angeles.

SYMPOSIUM ON FRACTURES AND OTHER TRAUMAS

Tuesday 2:00-5:00 p.m.

ROBERT H. KENNEDY, M.D., F.A.C.S., New York, Chairman, Committee on Fractures and Other Traumas
 Presiding

Avulsions of the Skin CARLETON MATTHEWSON, JR., M.D., F.A.C.S., San Francisco, Professor of Surgery
 Stanford University School of Medicine
 Secondary Closure of Wounds HARRY C. BLAIR, M.D., F.A.C.S., Portland, Associate Clinical Professor
 of Orthopedics, University of Oregon Medical School
 Care of Acute Amputations of the Fingers WALTER C. GRAHAM, M.D., F.A.C.S., Santa Barbara, Attending
 Orthopedic Surgeon, Santa Barbara Cottage and Santa Barbara General Hospitals
 Fractures of the Lower End of the Humerus in Children JOHN C. WILSON, M.D., F.A.C.S., Los Angeles
 University of Southern California School of Medicine, Chief
 Clinical Professor of Orthopedic Surgery
 Orthopedic Staff, Children's Hospital
 Wounds of the Heart R. ARNOLD GRISWOLD, M.D., F.A.C.S., Louisville, Professor and Head, Department
 of Surgery, University of Louisville School of Medicine
 Acute Arterial Emergencies JERRE W. LORD, JR., M.D., F.A.C.S., New York, Instructor in Surgery, Cornell
 University Medical College
 Evaluation of Principles Concerned in Management of Trauma to the Kidney LAZARUS A. ORKIN, M.D.,
 F.A.C.S., New York, Chief of Clinic and Adjunct in Urology, Beckman Downtown Hospital.

SYMPOSIUM CANCER IS CURABLE

Tuesday 2:00-5:00 p.m.

GRANTLEY W. TAYLOR, M.D., F.A.C.S., Boston, Chairman, Cancer Committee, American College of
 Surgeons, Presiding

Value of Statistics in the Curability of Cancer BOWMAN C. CROWELL, M.D., Chicago, Associate Director
 American College of Surgeons and Director of the Department of Clinical Research
 Variables in Attainment of High Rates of Cancer Cures FREDERICK S. WETHERELL, M.D., F.A.C.S.,
 Syracuse, Senior Attending Surgeon, Syracuse Memorial Hospital, Chairman, Service and Medical
 Advisory Committee, New York State Division, American Cancer Society
 The Curability of Cancer in Children SIDNEY FARBER, M.D., Boston, Professor of Pathology, Harvard
 Medical School, Director, Division of Laboratories and Research, The Children's Medical Center,
 Boston
 Encouraging Excerpts from Recorded Cancer Experience FRED J. HODGES, M.D., Ann Arbor, Professor of
 Roentgenology, University of Michigan, Chairman, Department of Roentgenology, University Hospital
 Present Trends and Five Year Results of Cancer Therapy at Memorial Hospital in New York City FRANK E.
 ADAIR, M.D., F.A.C.S., New York, Associate Professor of Clinical Surgery, Cornell University Medical
 College, Attending Surgeon, Memorial Hospital
 Cures of Cancer at the Massachusetts General Hospital GRANTLEY W. TAYLOR, M.D., F.A.C.S., Boston
 Associate in Surgery, Harvard Medical School, Chairman, Cancer Committee, American College of
 Surgeons
 Five Year Cures in a University Hospital J. ELLIOTT SCARBOROUGH, M.D., F.A.C.S., Atlanta, Associate in
 Surgery, Emory University School of Medicine, Attending Surgeon and Director of Tumor Clinic,
 Emory University Hospital
 Five Year Cures in Bronchogenic Carcinoma from the Chest Service of the Barnes Hospital EVARTS A.
 GRAHAM, M.D., F.A.C.S., St. Louis, Professor of Surgery, Washington University School of Medicine,
 Surgeon-in-Chief, Barnes Hospital
 Five Year Cures in Carcinoma of the Large Intestine GEORGE V. BRINDLEY, M.D., F.A.C.S., Temple
 Texas, Lecturer in Surgery, University of Texas Medical School, Chief Surgeon, Scott and White
 Clinic and R. R. WHITE, M.D., Temple, Surgeon, Scott and White Clinic
 Cancer of the Colon and Rectum with Particular Reference to the Results of Surgical Treatment CLAUDE
 F. DIXON, M.D., F.A.C.S., Rochester, Professor of Surgery, Mayo Foundation and Surgeon, Mayo
 Clinic and R. LEE CLARK, JR., M.D., F.A.C.S., Houston, Director and Surgeon in Chief, The Univer-
 sity of Texas M.D. Anderson Hospital for Cancer Research
 Experiences with the Curability of Cancer in Connecticut EDWARD J. OTTENHEIMER, M.D., F.A.C.S.,
 Willimantic, Chief Surgical Service, Windham Community Memorial Hospital
 Five Year Results of Treatment Ellis Fischel State Cancer Hospital JOHN MONLIX, M.D., Columbia
 Missouri, Chief Surgeon, Ellis Fischel State Cancer Hospital
 Cancer Cures in a Veterans Administration Hospital CHARLES B. PUESTOW, M.D., F.A.C.S., Chicago
 Professor of Surgery, University of Illinois College of Medicine, Chief Surgical Service, Veterans
 Administration Hospital, Hines.

Report of Five Year Cures of Cancer from Private Practice and from King County Hospital. DONALD A. TRUFLOOD, M.D., F.A.C.S., Seattle. Chief, Department of Surgery, Doctors Hospital, Director, Neoplastic Clinic, King County Hospital.

SYMPOSIUM ON CANCER

Wednesday 2:00-5:00 p.m.

- GRANTLEY W. TAYLOR, M.D., F.A.C.S., Boston, Chairman, Cancer Committee, American College of Surgeons, Presiding.
 Tumors of the Central Nervous System. EDWIN H. B. BERRY, M.D., F.A.C.S., San Francisco, Assistant Clinical Professor of Surgery, University of California Medical School.
 Cancer of the Stomach. A Survey of 1004 Cases. STANLEY I. LAWY, M.D., F.A.C.S., Chicago, Assistant Professor of Surgery, University of Illinois (Rush) College of Medicine.
 Lymphoma. SIDNEY FARRER, M.D., Boston, Professor of Pathology, Harvard Medical School.
 Early Diagnosis of Prostate Trepanment of Cancer of Urinary Bladder. CILBERT J. THOMAS, M.D., F.A.C.S., Beverly Hills, Associate Clinical Professor of Surgery (Urology), University of Southern California School of Medicine.
 Tumors of the Pelvis. DAVID P. SLAUGHTER, M.D., F.A.C.S., Chicago, Assistant Professor of Surgery, University of Illinois College of Medicine.
 Cancer of the Ovary. JOE A. MEIGS, M.D., F.A.C.S., Boston, Clinical Professor of Gynecology, Harvard University Medical School.

SYMPOSIUM ON GRADUATE TRAINING IN SURGERY AND THE SURGICAL SPECIALTIES

Thursday 3:00-6:00 p.m.

- FREDERICK A. CHAFF, M.D., F.A.C.S., Chairman, Committee on Graduate Training in Surgery, Presiding.
 Progress in Graduate Training.
 FREDERICK A. CHAFF, M.D.
 The Inclusion of the Patient in the Resources for Graduate Training in Surgery. THOMAS H. SWIFT, M.D., F.A.C.S., Minneapolis, Clinical Assistant Professor of Surgery, Division of Urology, University of Minnesota.
 The Graduate Training Requirement for Specialization. Thoracic Surgery. WILLIAM E. ADAMS, M.D., F.A.C.S., Chicago, Professor of Surgery, University of Chicago, The School of Medicine of the Division of Biological Sciences.
 Essentials of Orthopedic Graduate Training and Acceptable Alternatives in Training. LEROY C. ASBOTT, M.D., F.A.C.S., San Francisco, Professor of Orthopedic Surgery, University of California School of Medicine, Chief, Orthopedic Service, Children's Hospital.
 Essentials of and Proposed Changes in Graduate Training Requirement for Specialization I. Urology. CILBERT J. THOMAS, M.D., F.A.C.S., Beverly Hills, Clinical Associate Professor of Surgery (Urology), University of Southern California School of Medicine.

PRESIDENTIAL MEETING

Monday 8:15-10:30 p.m.—The Philharmonic Auditorium

- ARTHUR W. ALLEN, M.D., F.A.C.S., Boston, President, American College of Surgeons, Presiding.
 Professional—Officers, Regents and Distinguished Guests.
 Vocational.
 The Most Reverend J. FRANCIS A. MCINTYRE, Los Angeles, Archbishop, Archdiocese of Los Angeles.
 Address of Welcome.
 DONALD G. TOLLESON, M.D., F.A.C.S., Los Angeles.
 Chairman, Committee on Arrangements.
 Introduction of Distinguished Guest.
 IRVIN ARELL, M.D., F.A.C.S., Louisville.
 Chairman, Board of Regents.
 Address of the Retiring President, Looking Forward.
 ARTHUR W. ALLEN, M.D.
 Inauguration of Officers:
 Presented by THOMAS F. JOYCE, M.D., F.A.C.S., Cleveland;
 Retiring First Vice President.

First Vice President HOWARD A. PATTERSON, M.D., F.A.C.S., New York
 Second Vice President CARL H. MCCASKEY, M.D., F.A.C.S., Indianapolis
 President DALLAS B. PHEMISTER, M.D., F.A.C.S., Chicago
 The Third Martin Memorial Lecture Some Aspects of the Development of Intrathoracic Surgery
 CLARENCE CRAWFORD, M.D., Stockholm, Sweden, Professor of Surgery, Karolinska Mediko-kirurgiska
 Institutet

CONVOCATION

Friday 8:15-10:30 p.m. — The Philharmonic Auditorium

DALLAS B. PHEMISTER, M.D., F.A.C.S., Chicago, President, American College of Surgeons, Presiding
 Processional—Initiates Officers, Regents and Distinguished Guests

Invocation
 The Right Reverend Francis Eric Bloy, Los Angeles, Bishop, Diocese of Los Angeles

Presentation of Initiates for Fellowship
 IRVING ABELL, M.D., F.A.C.S., Louisville

Chairman, Board of Regents
 Fellowship Pledge Recital by Initiates
 Conferring of Fellowships by the President

DALLAS B. PHEMISTER, M.D.
 Conferring of Honorary Fellowships

The President
 Fellowship Address Hereditary Errors in Metabolism
 GEORGE W. BEADLE, Ph.D., Pasadena, California

Professor and Chairman, Department of Biology, California Institute of Technology
 Recessional
 Reception by the Officers and Regents for the Initiates and Fellows

ANNUAL MEETING
BOARD OF GOVERNORS OF THE COLLEGE

Wednesday 12:15 p.m. — 2:00 p.m. — West Gold Room, Ambassador Hotel

DALLAS B. PHEMISTER, M.D., F.A.C.S., Chicago, President, American College of Surgeons, Presiding
 Statement by the Chairman of the Board of Regents
 IRVING ABELL, M.D., F.A.C.S., Louisville

Brief Reports on the Activities, Problems and Progress of the American College of Surgeons
 ARTHUR W. ALLEN, M.D., F.A.C.S., Boston, Immediate Past President
 FREDERICK A. COLLIER, M.D., F.A.C.S., Ann Arbor, Regent

Discussion by Governors and Regents

ADJOURNED MEETING
BOARD OF GOVERNORS OF THE COLLEGE

Thursday 1:30 p.m. — Ballroom, The Biltmore Hotel

DALLAS B. PHEMISTER, M.D., F.A.C.S., Chicago, President, American College of Surgeons, Presiding
 Report of Committee on Nominations to the Board of Governors
 Election of Regents of the College

ANNUAL MEETING, FELLOWS OF THE COLLEGE

Thursday 1:45-3:00 p.m. — Ballroom, The Biltmore Hotel

DALLAS B. PHEMISTER, M.D., F.A.C.S., Chicago, President, American College of Surgeons, Presiding
 Report of Committee on Nominations
 Election of Officers and Governors of the College
 Report of the Treasurer
 DALLAS B. PHEMISTER, M.D., Chicago, Treasurer
 EDWARD G. SANDROK, Comptroller
 Cancer Committee
 CRANTLEY W. TAYLOR, M.D., F.A.C.S., Boston, Chairman

CLINICAL CONGRESS 1948

Esophageal Wound Healing An Experimental Study ALFONSO TOPETE M.D., JAMES M. FRITZ M.D. and WILLIAM E. ADAMS M.D. F.A.C.S. Chicago Illinois University of Chicago College of Medicine.
The Limitations of a Gastric Drainage Operation Upon the Effectiveness of Vagotomy C. WALTER LILLIE HEI M.D., Minneapolis Minnesota University of Minnesota Medical School
The Effect of Vagotomy on Intestinal Motility SALMAN FAIK M.D. F.C. MANN M.D. and JOHN H. GRINDLAY M.D. F.A.C.S. Rochester Minnesota Mayo Foundation
A New Parasympathetic Stimulant—Ethyl 3,3 Dimethylallyl Barbituric Acid Its Effect on Gastric Secretion C. M. BALLEW M.D., R. L. NABLE, M.D. D. R. WEBSTER, M.D., and J. R. MCCARRISTON M.D. Montreal Quebec. McGill University Faculty of Medicine
The Use of Buffer and Thrombin in the Control of Gastrointestinal Hemorrhage BYRNE M. DALY M.D. Detroit Michigan Wayne University College of Medicine
The Intraduodenal Spread of Malignant Gastric Lesions CHARLES P. MARVIN M.D. Atlanta Georgia
A Study to Determine a Method of Estimating the Proportion of the Stomach Removed in Partial Gastrectomy WESTON A. HEINRICH M.D. Evansville Indiana Mayo Foundation

Thyroid, Thymus Lungs

8 30 a.m. Tuesday—Ballroom The Billmore Hotel

FREDERICK A. COLLIER M.D. F.A.C.S. Ann Arbor Professor of Surgery University of Michigan Medical School Presiding
Thyroid Cancer A Problem of Surgery and Pathology JOHN C. MCCLINTOCK M.D., F.A.C.S. and GUSTAVUS H. KLINCK, JR. M.D. Albany New York Albany Medical College.
An Experimental Study of the Behavior of Residual Thyroid Tissue Following Subtotal Thyroidectomy THOMAS LEDWICH M.D. FLOYD MARCHI, M.D. MAYO SOLEY M.D. EARL MILLER M.D., GEORGE YEE, M.D. KENNETH SCOTT Ph.D. and HORACE J. MCCORMIE M.D. F.A.C.S. San Francisco California. University of California Medical School
The Effect of Iodine on the Rat Thyroid Activated by Cooling ARTHUR J. LESSER, M.D. RICHARD J. WINKLER, Ph.D. and J. B. MICHAELSON M.S. Los Angeles, California University of Southern California School of Medicine
A Clinicopathologic Study of Tumors of the Thymic Region PHILIP W. SMITH M.D., Ann Arbor Michigan University of Michigan Medical School
The Dyphenylamine Reaction of Human Serum. SOAD NIAZI, M.D. and DAVID STATE, M.D. F.A.C.S. Minneapolis, Minnesota. University of Minnesota Medical School
Management of Unilateral Total Bronchiectasis by Pneumectomy BYRON H. EVANS M.D. Ann Arbor Michigan. University of Michigan Medical School
Prevention of Mediastinal Shift After Pneumectomy with a Polythene Bag An Experimental Study JOHN H. GRINDLAY M.D. F.A.C.S. J. R. RYDELL, M.D. and O. THERON CLAGETT M.D. F.A.C.S. Rochester Minnesota Mayo Foundation.
The Anatomical Guide to the Intersegmental Plane. BEATTY HAIN RAMSAY M.D. Cambridge Massachusetts.
Segmental Resection of the Upper Pulmonary Lobe for Benign Disease A Plea for Conservation of Lung Tissue ALFRED HURWITZ, M.D. Newington Connecticut Veterans Administration Hospital.
An Evaluation of Oxygen Therapy JAMES B. HAMMOND M.D. RALPH C. RICHARDS M.D. and PHILIP B. PRICE, M.D. F.A.C.S. Salt Lake City Utah University of Utah School of Medicine
A New Type of Artificial Respiration STANLEY J. SARNOFF M.D. E. HARDENBERGH, and J. L. WHITE TENBERGER, M.D. Boston Massachusetts Harvard School of Public Health
Experimental Embolism of Selected Portions of the Pulmonary Arterial Bed MASAOKI HARA M.D. and JOHN R. SMITH M.D. St. Louis Missouri. Washington University School of Medicine

Surgery of the Heart and Great Vessels

8 30 a.m. Wednesday—Philharmonic Auditorium

ROBERT E. GROSS, M.D. F.A.C.S. Boston Assistant Professor of Surgery Harvard Medical School Presiding
Treatment of Aortic Aneurysms By Wrapping with a Foreign Body J. KARL POPPE M.D. F.A.C.S. Portland Oregon
The Control of Hemorrhage From Experimental Wounds of the Coronary Vessels. HOWARD G. REISE M.D. and HILGER P. JENKINS M.D. F.A.C.S. Chicago Illinois University of Illinois College of Medicine and Woodlawn Hospital
Resection of Left Auricular Appendage A Prophylaxis in the Treatment of Recurrent Arterial Embolism JOHN L. MADSEN M.D. Brooklyn New York. Long Island College of Medicine and Kings County Hospital.

- Extirpation of the Auricular Appendage in the Dog. WALTER J. BURDETTE, M.D., New Orleans, Louisiana. Louisiana State University School of Medicine.
- Resection and Grafting of the Thoracic Aorta with Minimal Interruption of the Circulation. CHARLES A. HUTNAGEL, M.D. Boston, Massachusetts. Harvard Medical School.
- Studies of Intraradial and Intrafemoral Arterial Pressure and Arterial Pulse Contours Before and After Corrective Surgical Procedures for Coarctation of the Aorta. GEORGE E. BROWN, M.D. Twin Falls, Idaho. O. THERON CLAGETT, M.D. F.A.C.S. H. B. BURCHELL, M.D. and E. H. WOOD, M.D. Rochester, Minnesota. Mayo Foundation.
- Pump Oxygenator to Replace the Heart and Lungs for Brief Periods. CLARENCE DEWITS, M.D. EARL E. KARLSON, M.D., and DARRELL E. WESTOVER, M.D. Minneapolis, Minnesota. University of Minnesota Medical School.
- Establishment of Extra Cardiac Shunts for Treatment of Stenosed Cardiac Valves. ROBERT E. GROSS, M.D. F.A.C.S. E. CONVERSE PEIRCE, II, M.D. HAROLD F. RHINKLANDER, M.D., and ALEXANDER H. BILL, JR., M.D. Boston, Massachusetts. Harvard Medical School and Children's Hospital.
- The Rationale and Technique of Extracorporeal Vascular Shunts. LESTER BLUM, M.D. F.A.C.S. and SAMUEL J. MCGIMON, M.D. New York, New York. Mount Sinai Hospital.
- The Creation and Closure of Artificial Atrial Septal Defects in the Dog. W. B. MARTIN, M.D., H. E. ESECKY, Ph.D. H. B. BURCHALL, M.D. and J. EDWARDS, M.D. Rochester, Minnesota. Mayo Foundation.
- The Correction of Aortic Insufficiency in Dogs with an Artificial Aortic Valve. J. MOORE CAMPBELL, M.D. F.A.C.S. Oklahoma City, Oklahoma. University of Oklahoma School of Medicine and University Hospitals.
- Experimental Superior Vena Caval Obstruction. Treatment by Vein to Vein and Auricle to Vein Anastomosis. FRANK GERRODE, M.D. JAMES YEE, M.D. and F. F. RUNDLE, M.D. San Francisco, California. Stanford University School of Medicine.
- Superior Vena Caval Obstruction—A Clinical Study. CHESTER B. NOYER, M.D. San Francisco, California. Stanford University School of Medicine.
- Experimental Lesions of the Pulmonary Artery Associated with Patent Ductus Arteriosus. SAKFORD E. LEEDE, M.D. F.A.C.S. San Francisco, California.
- Quantitative Production of Myocardial Necrosis. Experimental Study with a New Method. CARL DAVIS, JR., M.D. C. B. TAYLOR, M.D. and O. H. AAR, M.D. Chicago, Illinois. Presbyterian Hospital and University of Illinois College of Medicine.
- Bones and Joints Infection. Skin Preparation. Hemostasis. Plastic Surgery.*
830 a.m. Wed. today—Ball room The Biltmore Hotel
- MICHAEL L. MASON, M.D. F.A.C.S. Chicago. Associate Professor of Surgery. Northwestern University Medical School, President.
- The Suction Socket for Above Knee Amputees. PAUL E. McMASTER, M.D. F.A.C.S. and ROBERT MAERT JR., M.D. F.A.C.S. Los Angeles, California. Veterans Administration Hospital.
- Bone Marrow Extirpation of Primary Neoplasms of Bone. J. F. UPHAM, M.D. J. R. MACDONALD, M.D. and R. K. GORMLEY, M.D. F.A.C.S. Rochester, Minnesota. Mayo Foundation.
- The Effect of Intramedullary Pinning on the Healing of Fractures—An Experimental Study. WILLIAM T. FITZ, JR., M.D. BROOKS ROBERTS, M.D. STANLEY I. SPOONT, M.D. and VERN W. RITTER, M.D. Philadelphia, Pennsylvania. University of Pennsylvania School of Medicine and Hospital of the University of Pennsylvania.
- The Anatomy and Physiology of Nerves to Diarthrodial Joints. ERNEST GARDNER, M.D. Detroit, Michigan. Wayne University College of Medicine.
- Streptomycin Therapy of Established Wound Suppuration. MAJOR EDWIN J. PULASKI and LIEUTENANT G. F. CONNELL, JR. M.C. U.S.A. Fort Sam Houston, Texas. Brooke General Hospital.
- The Prophylactic Use of Bacitracin in Experimental Clostridial Infections in Guinea Pigs. WILLIAM R. SANDUSKY, M.D. F.A.C.S. and CONSTANCE F. KEEBLE, B.S. Charlottesville, Virginia. University of Virginia Hospital.
- Clinical Study of the Use of a Synthetic Detergent Combined with a 2, 2-Dihydroxy-3, 5, 6-trimethyl-6-Hexachlorodiphenylmethane (G-11) for Disinfection of the Skin. BAUMLEY S. FREEMAN, M.D. F.A.C.S. and THOMAS K. YOUNG, JR., M.D. Temple, Texas. McCloskey Veterans Administration Hospital.
- The Use of Quaternary Ammonium Compound for the Surgical Disinfection of Hands. HENRY SWAN, M.D. RICHARD L. GONZALEZ, M.D. ALLEN HARRIS, M.D. C. COULSON and M. L. HOPWOOD. Denver, Colorado. University of Colorado School of Medicine.
- A Study of Action of Detergents on Skin by Biological Methods. RICHARD L. THIRLBY, M.D. and A. BURGESS VIAI, M.D. Ann Arbor, Michigan. University of Michigan Medical School.
- Talc Granuloma—A Survey of Its Incidence and Significance. WILLARD B. ROSS, M.D. and JOSEPH M. LURITZ, M.D. Wood Wisconsin. Marquette University School of Medicine and Veterans Administration Hospital.

Nonreactive Absorbable Glove Powder RAYMOND W. POSTLETHWAIT M.D. H. LEE HOWARD M.D. and PAUL W. SCHANIER M.D. Durham, North Carolina. Duke University School of Medicine.
An Experimental Evaluation of a New Glove Powder for Use in the Operating Room HOWARD C. NAFF ZIGER, M.D. F.A.C.S., THOMAS LEDWICH M.D. FLOYD MARCINI, M.D. and HORACE J. MCCORKLE M.D. F.A.C.S. San Francisco California. Department of Experimental Surgery University of California Medical School.

The Effect of Heparin on Gelfoam Hemostasis W. J. GROVE M.D. and C. W. VERMEULEN M.D. Chicago Illinois. University of Illinois College of Medicine.

The Use of Skin Grafts in Cleft Palate Repair to Improve Speech Results HAMILTON BAXTER M.D. Montreal Quebec. McGill University Faculty of Medicine and Royal Victoria Hospital.

Protein Fluid and Salt Balance Thrombosis and Embolism

8:30 a.m. Thursday—Philharmonic Auditorium

ALTON OCHSNER, M.D. F.A.C.S. New Orleans. William Henderson Professor and Director. Department of Surgery. Tulane University of Louisiana School of Medicine. Presiding.

The Magnitude of Base Loss in Fecal Fistulae Combined with Continuous Suction Drainage of the Stomach EVERETT IDRIS EVANS M.D. F.A.C.S. and K. KELLER VAN SLYKE, M.D. Richmond Virginia. Medical College of Virginia.

Abnormal Fluid Distribution in Intractable Postoperative Hypochloremia Further Aggravated by Saline Therapy RICHARDS P. LYON M.D. JOSEPH R. STANTON M.D. F.A.C.S. EDWARD D. FREIS M.D., and REGINALD H. SMITHWICK, M.D. F.A.C.S. Boston Massachusetts. Boston University School of Medicine and Massachusetts Memorial Hospitals.

Response to Parenteral Glucose of Normal Kidneys and of Kidneys of Postoperative Patients DONALD R. COOPER, M.D. and L. VIVIAN JOB Ph.D., Ann Arbor Michigan. University of Michigan Medical School.

The Influence of Adrenal Cortical Hormone in Hypochloremic Alkalosis K. KELLER VAN SLYKE M.D. and EVERETT IDRIS EVANS, M.D. F.A.C.S. Richmond Virginia. Medical College of Virginia.

An Experimental Study of Intravenous Alimentation in the Dog C. MARTIN RHODE M.D. Philadelphia Pennsylvania. University of Pennsylvania School of Medicine.

Massive Hepatic Necrosis in the Protein Depleted Partially Hepatectomized Rat R. L. ESTRADA M.D. Z. A. SIMPSON M.D. and HARRY M. VARS, Ph.D. Philadelphia, Pennsylvania. University of Pennsylvania School of Medicine.

Human Albumin Nitrogen Balance DONALD J. FERGUSON M.D. DAVID STATZ M.D. F.A.C.S., and IVAN D. BARONORSKY, M.D. Minneapolis Minnesota. University of Minnesota Medical School.

Some Physiologic Effects of Prolonged Administration of Human Albumin NICHOLAS S. GINSBERG, M.D. CECILIA RIEGEL, M.D. WILLIAM W. GLENN, M.D. JAMES NIXON M.D. DOUGLAS W. SANDERS, M.D. and MELVIN SOBEL, M.D. Philadelphia Pennsylvania. University of Pennsylvania School of Medicine and Hospital of the University of Pennsylvania.

The Influence of Fat in the Diet Upon Nitrogen Metabolism and Liver Protein Regeneration HARRY M. VARS Ph.D., and CHARLES E. FRIEDGOOD M.D. Philadelphia Pennsylvania. University of Pennsylvania School of Medicine.

Measurements of Healing Strength of a Standard Wound in Anemic or Starvation States and After Treatment With Blood Transfusions or Refeeding YOSHIO SAKO M.D. ARNOLD KREIMEN M.D. and RICHARD L. VARCO, M.D. Minneapolis Minnesota. University of Minnesota Medical School.

Pulmonary Embolism RICHARD H. LILLIE M.D. and ROBERT W. BUXTON M.D. F.A.C.S. Ann Arbor Michigan. University of Michigan Medical School.

Experimental Pulmonary Embolism BYERS W. SHAW M.D. WILLIAM D. HOLDEN M.D. F.A.C.S. DONALD B. CAMERON M.D. PATRICK C. SHEA JR. M.D. and JOHN H. DAVIS, JR. M.D. Cleveland Ohio. Western Reserve University School of Medicine and University Hospitals.

The Effect of Moderate Degrees of Dicumarol Induced Hypoprothrombinemia on Experimental Intravascular Thrombosis J. FORBES ROGERS, M.D., RAYMOND J. BARRETT M.D. and CONRAD R. LAM M.D. F.A.C.S. Detroit Michigan. Henry Ford Hospital.

Clinical Studies on the Heparin Cofactor WILLIAM D. HOLDEN M.D. F.A.C.S. JOHN H. DAVIS, JR. M.D. and JOHN W. COLE, M.D. Cleveland Ohio. Western Reserve University School of Medicine.

Experimental Venous Thrombosis and Its Prevention by Dicumarol DONALD B. CAMERON M.D., WILLIAM D. HOLDEN M.D. F.A.C.S., BYERS W. SHAW, M.D. and PATRICK C. SHEA JR., M.D. Cleveland Ohio. Western Reserve University School of Medicine.

Neurosurgery Radioactive Substances Irradiation

8:30 a.m. Thursday—Ballroom. The Biltmore Hotel

CLARENCE E. STAFFORD M.D. F.A.C.S. Los Angeles, Acting Head. Department of Surgery. College of Medical Evangelists. Presiding.

- Anhidrosis as Measure of Sympathetic Denervation. GRACE M. ROTH, Ph.D. and WINCHELL McCRAIG, M.D. F.A.C.S. Rochester, Minnesota. Mayo Foundation.
- Continuous Procaine Paravertebral Sympathetic Blocks. J. R. THOMASON, M.D. and WILLIAM H. MORTZ, M.D. Salt Lake City, Utah. University of Utah School of Medicine and Salt Lake General Hospital.
- A Study of the Action of Sympathomimetic Drugs in Combination with Intrathecal Anesthetic Agents. JOHN C. HENDERSON, M.D., LOUIS L. STOLER, M.D. and I. B. TAYLOR, M.D. Detroit, Michigan. Wayne University College of Medicine and City of Detroit Receiving Hospital.
- The Effects of Position on the Cerebral Circulation of Man. H. A. SHENKIN, M.D. W. G. SCHREURMAK, M.D. and E. B. SUTZ, M.D. Philadelphia, Pennsylvania. University of Pennsylvania School of Medicine and Hospital of the University of Pennsylvania.
- The Role of Nerve Blocks in Restoring the Balance of Traumatic Cord Bladders. ERNEST BORN, M.D., A. L. COMARR, M.D. and S. H. MOULTON, M.D. Van Nuys, California. Birmingham Veterans Administration Hospital.
- Clinical Evaluation of Radiofluorescein as an Aid in the Localization of Brain Tumors. SAMUEL W. HUNTER, M.D., LAURENCE A. FRENCH, M.D. and GEORGE E. MOORE, M.D. Minneapolis, Minnesota. University of Minnesota Medical School.
- Distribution of Trace Doses of Methionine Tagged with Radio Sulfur in Normal and Neoplastic Tissues. ALAN J. KARMEN, M.D., SAMUEL W. HUNTER, M.D., GEORGE E. MOORE, M.D. and CLAUDE HITCHCOCK, M.D. Minneapolis, Minnesota. University of Minnesota Medical School.
- The Use of Radiocalcium Phosphorus for Diagnostic Study of Lesions of the Breast. HORACE J. MCCONKEY, M.D. F.A.C.S., B. A. LOWMEYER, M.D., H. GLENN BELL, M.D. F.A.C.S., and ROBERT STOKES, M.D. San Francisco, California. University of California Medical School.
- Changes in the Clotting Mechanism Associated with Total Body Exposure to Ionizing Irradiation. J. GARRETT ALLEN, M.D. F.A.C.S. Chicago, Illinois. University of Chicago College of Medicine and Argonne National Laboratory.
- A Comparison of Blood Volumes in Surgical Patients as Determined by Radioactive Phosphorus Tagged Red Cells and T-824 Dye. HERMAN M. NACHMAN, M.D., JOHN W. MOORE, Ph.D. and EVERETT IDEN EVANS, M.D. F.A.C.S. Richmond, Virginia. Medical College of Virginia.
- Radioactive Isotopes as Diagnostic and Prognostic Aids in Peripheral Vascular Disease. MORRIS T. FREEDELL, M.D. F.A.C.S., FERTON SCHAFNER, M.D. and WILLIAM J. PICKETT, M.D. F.A.C.S., Chicago, Illinois. Illinois Institute for Medical Research Cook County Hospital.
- Fluorescein as an Adjunct in the Treatment of Radionecrotic Ulcers. HERMAN RICE, M.D. and BROOKLYN S. FREEMAN, M.D. F.A.C.S. Temple, Texas. McCloskey Veterans Administration Hospital.
- The Use of Beta Irradiation for Corneal Scarring. WILLIAM H. BOYD, M.D. Los Angeles, California.

Gall Bladder, Pancreas, Intestines, Miscellaneous

8:30 a.m. Friday—Philharmonic Auditorium

- WARREN H. COLE, M.D. F.A.C.S. Chicago. Professor of Surgery and Head, Department of Surgery, University of Illinois College of Medicine, Presiding.
- The Value of the Secretin Test in Surgery. HENRY DOUBILET, M.D. F.A.C.S. New York, New York. New York University College of Medicine.
- Gall Bladder Excretion Studies Following Gastric Resection. IVAN D. BARONOFFKY, M.D., DAVID GATZEL, M.D. and EDWARD A. BOYDEN, M.D. Minneapolis, Minnesota. University of Minnesota Medical School.
- An Experimental Method of Repair of Common Duct Strictures. JOHN R. SCHIELE, M.D., Chicago, Illinois. University of Illinois College of Medicine.
- The Role of the Sphincter of Oddi in the Prevention of Cholangitis. CHRISTEN LARSEN, M.D., WILLIAM T. FITZ, JR., M.D. and DAVID A. COOPER, M.D. Philadelphia, Pennsylvania. University of Pennsylvania School of Medicine and Hospital of the University of Pennsylvania.
- Total Pancreatectomy with Report of the Postoperative Physiological Studies. JACK GREENFIELD, M.D. and JACK H. SANDERS, M.D. Memphis, Tennessee. Veterans Administration Medical Teaching Group, Kennedy Hospital.
- The Cause of Death in Strangulation Obstruction. PAUL NEMETZ, JR., M.D., H. R. HAWTHORNE, M.D. F.A.C.S., D. L. DRABMAN, M.D. and ISIDORE COHEN, JR., M.D. Philadelphia, Pennsylvania. University of Pennsylvania School of Medicine.
- Effect of Streptomycin in Conditions Involving Infections of the Peritoneum. H. A. DAVIS, M.D. F.A.C.S. Los Angeles, California. Department of Surgery and Graduate School of Medicine, College of Medical Education.
- Experimental Mesenteric Vascular Occlusion. JOHN W. DEER, M.D. and RUDOLF J. NOER, M.D. F.A.C.S., Detroit, Michigan. Wayne University College of Medicine.

- The Use of Peritoneal Grafts to Reinforce Suture Lines Following Anastomosis of the Intestines SPENCER T. CHESTER, M.D. FREDERICK BINKLEY, M.D. H. GLENN BELL, M.D. F.A.C.S. and HORACE J. MCCORKLE, M.D. F.A.C.S. San Francisco California University of California Medical School
- The Surgical Treatment of Heredofamilial Polyposis of the Colon EARL J. BOXHINE, M.D. Los Angeles California
- Experimental Use of a Skin Lined Tube in the Greater Omentum J. R. MCCORRISTON, M.D. and D. W. MACKENZIE, JR., M.D. Montreal Quebec. McGill University Faculty of Medicine
- Studies on the Mechanism of Vomiting R. M. WHITROCK, M.D. and HENRY L. TIECHER, M.D. Ann Arbor Michigan University of Michigan Medical School
- The Use of Uretholine in Postoperative Distention CLARENCE E. STAFFORD, M.D. F.A.C.S. ARTHUR L. KUGEL, M.D. and ALEXANDER DEDERER, M.D. Los Angeles California College of Medical Evangelists
- The Physiological Effects of Curare Its Failure to Pass the Placental Membrane or Inhibit Uterine Contractions PHYLLIS HARROUN, M.D. and CARL W. FISHER, M.D. San Francisco California University of California Medical School

Vascular Surgery Blood Flow Urology

8:30 a.m. Friday—Ballroom The Biltmore Hotel

- CLARENCE J. BERNI, M.D. F.A.C.S. Los Angeles Professor of Surgery University of Southern California School of Medicine Preparing
- The Experimental Use of Vein Grafts in Establishing an Anastomosis Between the Portal and Systemic Systems EDWARD SHARKEY, M.D. Albany New York Albany Medical College
- Comparison of Suture Anastomosis Non-Suture Anastomosis and Polythene Tubing for Restoration of Circulation in the Critical Extremity ALLAN D. CALLOW, M.D. and C. STUART WELCH, M.D. F.A.C.S., Boston Massachusetts Tufts College Medical School
- Acceleration of the Velocity of Venous Flow in the Deep Veins of the Lower Extremity of Man by Local Compression JOSEPH R. STANTON, M.D. EDWARD D. FREIS, M.D. and ROBERT W. WILKINS, M.D. Boston Massachusetts Boston University School of Medicine
- The Effect of Tetra Ethyl Ammonium Chloride on Peripheral Blood Flow J. ROSS VEAL, M.D. F.A.C.S. JOHN N. SHADID, M.D. and WILLIAM L. JAMISON, M.D. Washington District of Columbia George Washington University School of Medicine
- The Use of Tetra Ethyl Ammonium Chloride as a Vasodilator in Peripheral Vascular Disease Its Effect on Sympathectomized Extremities JAMES B. FRENCH, M.D. WILLIAM E. ADOLPH, M.D. and THEODORE B. MASSILL, M.D. Los Angeles California College of Medical Evangelists and Birmingham Veterans Administration Hospital
- The Rationale of Therapy in Acute Vascular Occlusions Based upon Micrometric Observations HAROLD LAUFMAN, M.D. F.A.C.S. WAYNE B. MARTIN, M.D. and STANLEY W. TUELL, M.D. Chicago Illinois Northwestern University Medical School
- A Method for Recording Arterial Pressure and Pressure Pulse Contours and Changes in the Circulation of Patients Studied by This Method R. D. DRUMPS, M.D. K. F. EATHER, M.D. and L. H. PETERSON, Ph.D. Philadelphia, Pennsylvania Hospital of the University of Pennsylvania and University of Pennsylvania School of Medicine
- Local Reaction to Oxidized Cellulose and Gelatin Hemostatic Agents in Experimentally Contaminated Renal Wounds FRANK HIXMAN, JR., M.D. and KENWARD O. BARCOCK, M.D. San Francisco California University of California Medical School
- The Effect of Temporary Renal Vascular Occlusion on Renal Function CORNELIUS W. VERMEULEN, M.D., JOHN R. SCHEIBER, M.D. and ERNEST GIRALDI, M.D. Chicago Illinois University of Illinois College of Medicine
- Clinical Experiences with the Artificial Kidney JOHN T. MACLEAN, M.D. CHARLES B. RUPSTEIN, M.D. NANNIE K. M. DE LEEUW, M.D. and G. GAVIN MILLER, M.D. F.A.C.S. Montreal Quebec Royal Victoria Hospital and McGill University Faculty of Medicine
- Urinary Stress Incontinence Physiologic Restoration of Function of Sphincter Muscles ARNOLD H. KEGEL, M.D. F.A.C.S. Los Angeles California

Pinning of Fracture of Neck of Femur FRED ILFELD
Arthroscopy for Benign Tumor JOSEPH PELUSO
11:30-1:00 **Obstetrics and Gynecology Nonoperative Clinics**
Pregnancy Following Conservative Treatment for Pelvic Endometriosis. DANIEL R. MISHKILL and UMBERTO E. AGUIRRE
Early Rupture of the Uterus Before the Onset of Labor ALM. MCCARTHY and C. V. VON DER AHE.
Low Spinal Anesthesia in Obstetrics. A Report of 3,000 Cases. FRANK F. SCHADE and WILLIAM CALDWELL.

1:30-3:30. **Otorhinolaryngology Nonoperative Clinic**
Discussion Frontal Sinus Operation. J. McKEITHEN BROWN

Lesion of the Floor of Mouth and Neck. COLBY HALL.

Surgical Repair of Injuries of the 7th Nerve. FREDERICK VIOLA.

Correction of Septal Deformities. VICTOR GOODMILL.

Foreign Bodies in the Esophagus and Respiratory Tract. SMOON JESSIE

Malignancies of the Mastoid HAROLD BOYD.

Posthectomy of the Middle Ear. MAX PORTMAN

30-3 30. *Ophthalmology* Operative Clinics
Strabismus Demonstration of the O'Connor Clinch Operation and Recession of the Inferior Oblique Muscle. ALFRED ROBINSON

Cataract Extraction by the Castroviejo Section Technique. MAX ROCK NUGENT

Combined Extractions. STEPHEN POPOVICH

Glaucoma Decompression Operation. IRVIN SCHWIM

10-5 30. *Ophthalmology* Nonoperative Clinics

The Treatment of Corneal Scars by Beta Irradiation. WILLIAM H. BORN

The Tuschy Corneal Lens. MAX ROCK NUGENT

Complication Following Cataract Extractions. IRVIN SCHWIM

The Scleral Shortening Operation for Detachment of the Retina. (Motion picture in color). W. F. BORN

Latent II pertension and its Ophthalmoscopic Interpretations. STEPHEN POPOVICH

Thursday

8 00- 00 *General Surgery* Operative Clinics

Thyroidectomy. WILLIAM U. SULLIVAN and TENERO D. CUNEO

Radical Mastectomy. DONALD E. ROSS

Abdominal Perineal Resection of Rectum. WILLIAM H. D. NELSON

Colon Surgery. JAMES L. NEFF and D. A. GAZZARD

8 00- 00 *Orthopedic Surgery* Operative Clinics

Intermedullary Pinning of Fracture. Anterior Approach to Elbow Joint. HOWARD C. PIERCE and R. A. TAYLOR

Osteotomy and Excision of Non-Union of Neck of Femur by New Reverse Nail. GALE H. HAY

Subcutaneous Fasciotomy for Dupuytren's Contracture. JAMES H. LUCK

30- 00 *Orthopedic Surgery* Nonoperative Clinics

Final Results of Intermedullary Pinning of Fracture. ALFRED H. GALL

Slipped Upper Femoral Epiphysis. GALE H. HAY

Subcutaneous Fasciotomy (Motion picture). JAMES H. LUCK

Reconstruction of Elbow. JAMES H. LUCK and C. PIERCE

Friday

8 00- 00 *General Surgery* Operative Clinics

Tricectomy for the Duodenal. ROBERT B. RANNEY

Gall Bladder Surgery. WALTER M. HOLLEY and

Carcinoma of Bladder. FRED RICK and BEVETTE

Partial Gastrectomy. JAMES F. REGE

Resection Carcinoma of Esophagus. FRANK S. DOLLEY and LYMAN A. BREWER

Retropubic Prostatectomy. MORTON M. MAYERS

Thyroidectomy. DANIEL PORTMAN

30- 00 *General Surgery* Nonoperative Clinics

Radical Mastectomy (Motion picture in sound and color). DONALD E. ROSS

Mastectomy (Motion picture in color). JOSEPH GAYMAN

Sympathectomy (Motion picture). ROBERT B. RANNEY

Diabetes Mellitus Complicating Surgery. KENNEDY SMITH

ST. JOHN'S HOSPITAL, SANTA MONICA

Monday

8 00- 00 *General Surgery* Operative Clinics Surgery of the Gallbladder. ROBERT B. RANNEY

8 00- 00 *Obstetrics and Gynecology* Operative Clinics Cesarean Section (Bicornuate Uterus). B. H. W. TROTT

10 00- 00 *General Surgery* Operative Clinics Surgery of the Colon. G. ARNOLD STEVE

1 00- 00 *Orthopedic Surgery* Operative Clinics Laminectomy with Spinal Fusion. DONALD H. LEVITZ

Tuesday

8 00- 00 *General Surgery* Operative Clinics: Thyroidectomy. G. ARNOLD STEVE

8 00- 00 *Obstetrics and Gynecology* Operative Clinics: Anterior and Posterior Colporrhinoplasty and Kellie's Stitch. JAMES C. DOWLE and ALBERT C. MARRAS

10 00- 00 *General Surgery* Operative Clinics: Gastric Resection. MAX C. H. RABIN and DAVID H. ROSENBLUM

10 00- 00 *Orthopedic Surgery* Operative Clinics: Arthroscopy of the Knee. DONALD H. LEVITZ

Wednesday

8 00- 00 *General Surgery* Operative Clinics: Radical Mastectomy. JOHN F. KOWERS

8 00- 00 *Genitourinary Surgery* Operative Clinics: Retroperitoneal Prostatectomy. GILBERT J. THOMAS and FRED C. SCHILM ERGER

10 00- 00 *General Surgery* Operative Clinics: Vagotomy and Posterior Gastrectomy. FRANK L. HAY and H. RY J. LANGE

10 00- 00 *Plastic Surgery* Operative Clinics: Rhinoplasty. J. J. PIERCE

Thursday

8 00- 00 *General Surgery* Operative Clinics: Herniorrhaphy (Tantalum Suture and Tantalum Wire). MAX C. H. RABIN and DAVID H. ROSENBLUM

8 00- 00 *Obstetrics and Gynecology* Operative Clinics: Total Bilateral Hysterectomy. B. H. W. TROTT

10 00- 00 *General Surgery* Operative Clinics: Major Herniorrhaphy. FRANK L. HAY and HENRY J. LANGE

10 00- 00 *General Surgery* Operative Clinics: Exploration of Common Duct. G. ARNOLD STEVE

Final Pathological Nonoperative Clinic: Rapid Method of Surgical Tissue Diagnosis. G. H. HUNTER

Final Micro Laboratory Nonoperative Clinic: Photographic Study. G. H. HUNTER

COLLECTIVE REVIEW

THE EVOLUTION AND CLASSIFICATION OF HERNIAL OPERATIONS

CLAUDE C. BURTON M.D. F.A.C.S., Dayton Ohio

MANY authors notably Marcy(53), Halsted(38) Raaf(62) Mastin and Andrews(3) have given us an excellent account of the early technical development of herniotomy. Other authors have added fragmentary but important historical data incidental to their main theme on hernia. However there has been no attempt to trace systematically the evolutionary steps in the development of the numerous operative procedures used in the repair of hernia since the acceptance of the fundamental principles for reinforcing the wall as originally proposed by Bassini (1887) and Halsted(38) (1893). In this interim of a half century the many variants in technique which have been introduced are legion. They are generally known by the names of the surgeons who devised them rather than by their distinguishing anatomical features. As a result of this practice, it has become burdensome to remember the numerous techniques and their modifications and to correlate them anatomically. In certain instances the same operation may be identified in America by the name of one surgeon and by that of another on the European Continent. The perpetuation of such a system of proper names, in appreciation and recognition of those to whom we owe so much in the development of hernial operations, constitutes a frequent source of confusion and misunderstanding.

Because of the delinquency in standardizing and classifying the various technical procedures there is lacking a common denominator for the

Veterans Administration Center

discussion of the numerous methods of repair used in the radical cure of inguinal hernia. If an acceptable classification of hernial operations were available and the criteria for each were generally understood and sufficiently stressed there should be less indecision in choosing the operation that offers the greatest assurance of a cure of the type of hernia at hand. Consequently the greater our knowledge of herniology the more rational and selective will be our technique. To dispel the tendency toward adoption of a single technique for all hernias efforts should be directed toward the promotion of a better understanding of the genesis of hernia and to correlation of the fundamental principles underlying the repair of the varying structural deficiencies. For instance, illustrative of this evolutionary trend, the earlier authorities stressed the ablation of the sac as paramount others subsequently supported by the valid test of experience and familiar with concomitant parietal distortion were equally insistent on the necessity of strengthening the floor by repositioning of the cord a third group has laid much stress on the role of Cooper's ligament. The latter group recognized the value of previous surgical maneuvers but directed attention to the evaluation and correction jointly of the major underlying sacular or coexisting mural weakness. Because of these differing technological views and the lack of emphasis on criteria for their use, there still exists confusion in the mind of the junior surgeon whose training is our responsibility.

Therefore in order to clarify the existing confusion concerning the classification of a retinue of

hernial operations, we would like to propose three evolutionary periods of surgical development of hernial operations: (1) herniotomy (2) herniorrhaphy and (3) hemioplasty.

HERNIOTOMY

Generally the term herniotomy is applied indiscriminately to any operative procedure which may be employed in the radical cure of inguinal hernia. It is frequently used in this stereotyped sense in compiling statistical data. However herniotomy in its modern concept is understood to mean ligation and excision of the sac at the abdominal level of the internal ring without reinforcing the wall or displacing the cord. Therefore, in order to accurately define herniotomy it should be considered in relation to its evolutionary development as regards the level and methods of saccular obliteration. Consistent with this view herniotomy is classified into: (1) nonligation of the sac, kelotomy (2) low ligation of the sac, at the external ring (3) intermediate ligation of the sac, in the canal, and (4) high ligation of the sac, at the internal ring.

The sac may be obturated, obliterated or excised. Obturation of the internal ring was introduced by Maccewen in 1886 which preceded Bassini's classic technique. The redundant portion of the sac is fashioned and positioned at the abdominal side of the ring, and the hiatus is plugged to prevent egress of the hernia. Unfortunately but few surgeons were able to duplicate Maccewen's results. The second method of saccular disposal is nonoperative: the sac is obliterated by agglutination of its contiguous surfaces. To accomplish this a local aseptic peritonitis, either mechanical or chemical, is produced following which apposition of the collapsed walls of the sac is maintained until synthesis occurs. This technique cannot be satisfactorily controlled; it is uncertain its use is followed by many relapses, and it is practically impossible to totally obliterate the sac by this method. The ideal disposal of the sac is by ligation and total excision with resultant primary healing of the contacting serosal surfaces. It possesses the advantages of being perfectly controlled, is certain and safe, and is the method used exclusively in all modern operative procedures.

Nonligation of the sac—kelotomy (Fig. 1a) With the coming of the Renaissance, the mutilating and emasculating operations of the Dark Ages, in which the cord and testis were sacrificed, were abandoned and herniology of the heyday of the Greek civilization was revived. Early in the Sixteenth Century Pierre Franco was the first

surgeon with sufficient daring and courage to relieve strangulation by cutting the constricting ring which prevented its reduction. The technique of Franco's kelotomy was undertaken only as an emergency operation after taxis had failed. In that early period of hernial surgery the sole aim of the surgeon was life-saving. He discharged his responsibility in the treatment of hernia when the constriction had been released and the contents of the sac had been reduced.

Low ligation of the sac—at external ring (Fig. 1b) Impressive though the operation of kelotomy was when judged by the standards of that period, it was soon recognized that incising of the constricting band was only a temporizing measure. The remote results were very discouraging, as was shown by the appalling number of relapses. In retrospect, one could not expect the results to be otherwise as the sac was not obliterated nor was the wall repaired. To prevent the return of the hernia there was obviously need for technical improvement. Other contemporary methods proposed included (a) ligation of the cord and sac together with the use of a gold thread, as introduced by Bernard Metta (b) ligation of the sac alone, exercising care in preserving the cord (first conceived by Gerardus of Metta, and subsequently employed in the middle of the same century by the illustrious Ambroise Paré) (c) exposure of the external ring and suturing the sac and pillars together. Soan, Czerny and Banks were the chief proponents of this method. Toward the latter part of the Seventeenth Century and the beginning of the Eighteenth Century many surgeons became convinced of the therapeutic value of surgery for incarcerated hernia. The greatest anatomists of that day Petit, Cooper, Richter, and DuRoi were staunch supporters of herniotomy.

The operation which gained the widest recognition in European countries and in America consisted of ligation of the sac at the external ring and suturing the pillars around the cord to reduce the size of the ring. Among those surgeons contributing much toward standardization of this operative procedure were Marcy (53) (1881) of Boston, who represented the consensus of American surgeons Steel (1874) of England, who occupied a similar position among his colleagues in the British Isles and Czerny (1877) who expressed the crystallized thought of the continental surgeons.

Intermediate ligation of the sac—in the canal (Fig. 1c) It was becoming increasingly apparent to the most experienced surgeons that the higher the obliteration of the sac the more successful the

Fig 1. Herniotomy. Transsection of sac. Evolutionary steps in the progressively higher ligation of the sac.

a, Illustrates simple incision of the sac preparatory to reduction of the hernia (nonligation—kelotomy).

b, The sac has been mobilized and ligated at the level of the pillars of the external ring (low ligation).

c, The sac is occluded in the canal with transfixion of the stump to the margins of rent in external oblique aponeurosis. At this period of surgical development the aponeurosis had not been opened (intermediate ligation, in canal).

d, Portrays total excision of the sac at internal abdominal ring. To remove the sac at this level necessitates incising of the external oblique aponeurosis, which was first performed by Championnière in 1881 (high ligation at internal ring).

1, Spermatic cord 2, external oblique aponeurosis 2a, medial flap and 2b lateral flap 3, internal ring 4, hernial sac 4a, incision of sac and 4b, ligated sac stump 5, external ring 6, fascia transversalis and 7, internal oblique muscle.

operation as shown by the better end-results. The barrier to higher saccular ligation was the aponeurotic ring. Efforts to overcome this obstacle resulted in the proposal of various ingenious methods to attain this objective, such as twisting plicating and positioning of the stump of the sac. Despite the handicap of poor exposure, attempts were made to ligate the sac in the canal a variable distance from the external ring. Ball (1884), Wood(81) (1885) Stoker (1887) and Bull (1890) twisted the mobilized sac which was either ligated in the canal, or the fundus was passed through a rent in the external aponeurosis and transfixed. MacEwen, McEwen and Barker conceived the idea of occluding the internal ring with a plug made from folding the sac and suturing it to the intra abdominal circumference of the internal ring. They further implemented the saccular occlusion by making taut the relaxed structures of the floor of the canal. These maneuvers were all done through the prenatally enlarged external ring. The next innovation in hernia repair was made by Lucas Championnière (1881) who incised the external oblique aponeurosis which exposed the cord, the underlying mural structures, and the peritoneal sac to the level of the internal ring. By this simple stroke of deepening the incision, a new surgical and anatomical horizon was bared which was destined to be a milestone in hernial surgery.

High ligation of the sac—at the internal ring (Fig 1d). The technique of total excision of the

sac was evolved in the last quarter of the Nineteenth Century during which the modern concept of hernia repair originated. The principle of total excision was not long in receiving general acceptance. However there soon developed divergent views on the reparative methods of strengthening the floor of the canal.

In America, the operation that classically exemplifies herniotomy ligation of the sac at the internal ring without repair of the wall or disturbing the position of the cord is generally known as Ferguson's operation. Illustrative of the investigative spirit which prevailed at that time is the quotation of Ferguson: "A careful analysis of failures, a painstaking research for hidden truth and a discernment of contestable premises are ever before the surgeon who hopes for more success, new discoveries and lasting operative procedures. Out of an abundant surgical experience he proposed classification of the operative procedures for the correction of hernia into two types: typical and combined. The typical operation consisted of total excision of the sac only. The combined or late, Ferguson operation went one step farther to include tightening of the internal ring and taking up the slack in the fascia transversalis by suturing the conjoined tendon to Poupart's ligament all the way to the pubic spine. The latter operation was designed primarily to correct the weakness in the medial portion of the canal. Halsted(39) in 1903 added a slight variant by employing the cre-

master muscle to reinforce the posterior wall of the canal, but omitted tightening of the internal ring. Russell, too, has been a staunch advocate of the anatomical operation of Ferguson although his experience was confined largely to hernias in children.

Much controversy still exists regarding the merits of various operative procedures in the treatment of hernia, and whether to attempt to reproduce the equivalent, anatomically and physiologically of the inguinal canal. However if one accepts the modern concept of herniotomy this operative procedure should be given preference over other methods in the presence of the following criteria: (1) incipient indirect hernia, (2) no dilatation of the internal abdominal ring, and (3) no coexisting parietal weakness.

HERNIORRHAPHY

Herniorrhaphy is the second major evolutionary step in the progressive repair of inguinal hernia. It includes transposition of the cord and reinforcing the floor of the canal, additive to high ligation of the sac.

Available statistics following herniotomy revealed excellent results in some patients but there was also a substantial number of failures. The reason for the failures attracted the attention of many of the most experienced surgeons in America and Europe. Faulty execution of the technique of sacular ablation perhaps accounted for some of the recurrences, but obviously this was not an adequate explanation in others. The unfavorable results of herniotomy became so serious at one time that it was looked upon as a challenge to the surgical management of hernia, and particularly the principle of sacular ligation. Moreover it was becoming increasingly apparent that some essential was lacking in the operation such as a more selective application of sacular excision or a modification of the operative technique if a higher incidence of permanent cures were to be attained. Previously all hernias were considered indirect, and the existing mural weakness secondary to the dynamics of the expanding sac. Although Heister described direct hernia in 1724 there followed a long interim (three-fourths of a century) before the practical application of the knowledge of this important discovery. Direct hernia had not been looked upon as due primarily to deficiency of the internal oblique muscle and subsequent attenuation of fascia transversalis, an anomaly quite different anatomically and embryologically from that existing in indirect hernia. With the recognition generally of the basic differences of indirect and direct hernias, there came

changes in technique directed toward repair of the floor in the latter to conform to the newer anatomical and clinical knowledge. The means by which repair of the wall was achieved constitutes the second phase in the operative treatment of hernia. In reality herniorrhaphy was devised to take up the slack in the posterior fascial boundary for the treatment of direct hernia.

Although displacement of the cord is not an absolute prerequisite to strengthening of the floor nevertheless its transposition has played such an important role in the development of herniorrhaphy that it is inseparably associated with this era of hernial surgery. The brilliant and enduring work of Bassini, Halsted (38) Andrews (3) and others has had great influence on the attitude of the profession in adopting the principle of relocation of the cord. While there is still lack of unanimity in regard to its most strategic position, the consensus of most surgeons is decidedly on the side of funicular displacement. However it is only fair to state that mellowed opinions of our most experienced surgeons in the field of herniology view the disposition of the cord to implement the repair of the wall as having been overemphasized in the literature from the standpoint of therapeutic results. Nevertheless, it would seem that in the evolution of hernial surgery the most acceptable, practical, and logical classification of herniorrhaphy is the one based upon repositioning of the cord.

CLASSIFICATION OF HERNIORRHAPHY

1. Subaponeurotic, or placement of the cord under the external oblique aponeurosis—Marcy 1881; Bassini, 1884 and 1887.

2. Extra-aponeurotic, or placement of the cord on the external oblique aponeurosis—Halsted, 1893.

3. Interaponeurotic, or placement of the cord between the external oblique flaps—Andrews, 1895; Guard, 1901.

4. Transfemoral, or placement of the cord in the femoral canal—Cheever 1923; Litsitsyn, 1934.

Subaponeurotic position of the cord (Marcy [53], 1881; Bassini [88a] (Fig. 2a). In that era of hernial surgery the acceptance of operative treatment for uncomplicated hernia was steadily gaining momentum and was rapidly reaching international recognition as the treatment of choice for all types of hernias. This was in distinct contrast to the prevailing attitude two decades previously when it was considered heresy to operate upon a patient with a hernia unless it was incarcerated or strangulated. The greatest restraint or obstacle to progress in hernial surgery at that

Fig 2 Herniorrhaphy Transposition of cord Herniorrhaphy is the second major evolutionary step in the surgical treatment of hernia. In essence it is the strengthening of the floor of the canal additive to high ligation of the sac. The distinguishing feature of this technique is the repositioning of the cord.

- a Subaponeurotically
- b Inter-aponeurotically
- c Extra-aponeurotically
- d Transfemorally While not a prerequisite of the operation there is usually concomitant imbrication of the aponeurotic flaps.

time was the high incidence of recurrence. In retrospect this apparent handicap to progress was in reality a blessing in disguise for it held in check unjustified enthusiasm and served to co-ordinate technical variants with advancement in anatomical knowledge.

The distinction of having been the first to transpose the cord in hernial repair has been accorded Marcy (1881) by Raaf (62) Andrews (3) and Joyce but, after reviewing Marcy's book, it would seem there is room for doubt as to the exact date of the initial performance of his operation. Three years later Bassini in 1884 through the application of knowledge gained from painstaking anatomical dissection of the inguinal region introduced an almost identical operation. The principle of Marcy and Bassini of relocating the cord was a radical departure from the previously existing conventional methods employed in the surgical treatment of hernia. The follow up results of Bassini's first series of 42 cases was so much better as compared to the results of other contemporary methods that most continental surgeons and subsequently surgeons of the United States adopted it as standard technique in the re-

pair of hernias. The Bassini principle (high ligation of the sac and reinforcing the floor of the canal by suturing the conjoined tendon to Poupart's ligament beneath the cord) has been more universally used than any other technique.

Extra-aponeurotic position of the cord (Halsted [38] 1893) (Fig 2c) Independently and almost simultaneously Halsted developed a repair similar to Bassini's except that the cord was placed on the external oblique aponeurosis. In addition he proposed minor technical modifications such as ligating the superfluous veins of the cord to reduce its size and sectioning of fibers of the internal oblique and transversus abdominis to permit more lateral displacement of the internal abdominal ring. Halsted not only created a new canal by eliminating its obliquity but altered the relationship of the internal and external rings so that they superimposed. In many of the larger surgical clinics the cord is still placed extra-aponeurotically but the collateral technical variants which he described have been abandoned.

In our series of 3,850 hernia repairs on patients mostly in the fifth and sixth decades, we have routinely placed the cord on the imbricated

aponeurotic flaps. Our opinion as regards this maneuver has not been altered by careful statistical studies of our results. If care is exercised in mobilizing and displacing the cord, if trauma is avoided by using sharp dissection and if the aponeurotic flaps are imbricated so as to cause no constriction of the cord as it passes through the external ring testicular atrophy is an exceptionally rare sequela. In most instances, testicular complications arise from excessive trauma or incomplete hemostasis in the freeing of the scrotal sac. In a series of 161 consecutive hernia repairs testicular atrophy occurred in only seven instances. It is generally agreed that the superficial position of the cord is not an objectionable feature because of its liability to trauma in laborious occupations. The parietal relationship of the cord does not affect its circulation or the testicular functions. The slitting perpendicularly of the lateral flap at the exit of the cord to avoid funicular constriction as proposed by Stetten in 1920 is now seldom done.

Theoretically the objective of the early Halsted procedure was an attempt at formation of a solidly fused trilaminar aponeurotic wall guarding the strategically weak points, i.e. the abdominal ring and the floor of the medial inguinal triangle.

Interaponeurotic position of the cord (Andrews [3] 1893 Girard, 1901) (Fig 2b) The interaponeurotic relationship of the cord initially described by E. W. Andrews was a logical outgrowth of a wide surgical experience. He also overlapped the aponeurotic flaps however this feature of the repair had been employed by Lucas Championniere and Halsted. Andrews traveled extensively and had personally observed the technique of surgeons pre-eminent in this special field. At first he restricted his technique to those cases having a large gap in the fascial boundary of the floor of Hesselbach's triangle (direct hernia) but the results were so gratifying that it soon became the routine repair in his clinic. Andrews was aware of the principles of Bassini's repair in which the cord was placed subaponeurotically, and similarly knew that Halsted advocated the extra-aponeurotic relationship. He considered the funicular position of less importance than his contemporaries, and only incidental to the creation of a fundamentally sound wall. The primary purpose of this technique is to strengthen and guard the internal abdominal ring which is the gateway of indirect hernias. It was his contention that if sufficient tendinous barriers were placed at the internal ring it would prevent egress of the hernia. Andrews also insisted that the suturing of the internal oblique fibers to the inguinal ligament is unphysiological, further

distorts the musculature by interfering with its contractions, and actually predisposes to weakness of the abdominal wall in the medial angle of the canal. This observation of Andrews has been repeatedly confirmed and has played a significant role in the development of modern methods of repair.

For the sake of avoiding confusion, especially when referring to the literature of continental countries, it might be well to bear in mind that Girard of Switzerland described a technique similar to Andrews' interaponeurotic operation which postdated the latter by 6 years.

Transfemoral position of the cord (Cheever 1923) (Fig 3d) The latest innovation in the positioning of the cord was proposed by Cheever in 1923 when he introduced a new departure in the radical cure of hernia. In this technique the inguinal and lacunar ligaments are sectioned at their attachments to the pubic bone until the femoral canal is opened. The cord is then placed in the femoral canal. With this transposition, the cord and external iliac vessels have a common exit and the femoral ring becomes the external inguinal ring. The inguinal and lacunar ligaments are then rejoined to the pubic bone. Whether the transfemoral position of the cord possesses any advantages over other long recognized transpositions in the inguinal canal can be seriously questioned. There are no confirmatory statistical reports available on the follow-up results of the transfemoral technique.

While herniorrhaphy was a forward step, possessing many advantages over herniotomy and has resulted in a decided lowering of the incidence of recurrences, nevertheless it has its shortcomings and limitations. Therefore in order for this technique to be most effectual, it should be restricted to the following criteria (1) indirect inguinal hernia with prenatally large internal abdominal ring (2) laxity of the aponeurotic and fascial structures (3) indirect-direct or bilocular hernia and (4) normalcy of the inguinal ligament.

HERNIOPLASTY

Hernioplasty (herniofascioplasty) in a collective sense includes the more complex techniques used in hernia repair and is the third phase in the evolutionary development of hernial operations. It is the adoption of the principle of plastic reconstruction of the floor of the inguinal canal, usually with concomitant revision of the abdominal wall. The inguinal or ilipectineal (Cooper's) ligament, singly or combined, is utilized as anchorage for the medial parietal wall. In essence, it compounds our knowledge of hernia repair and

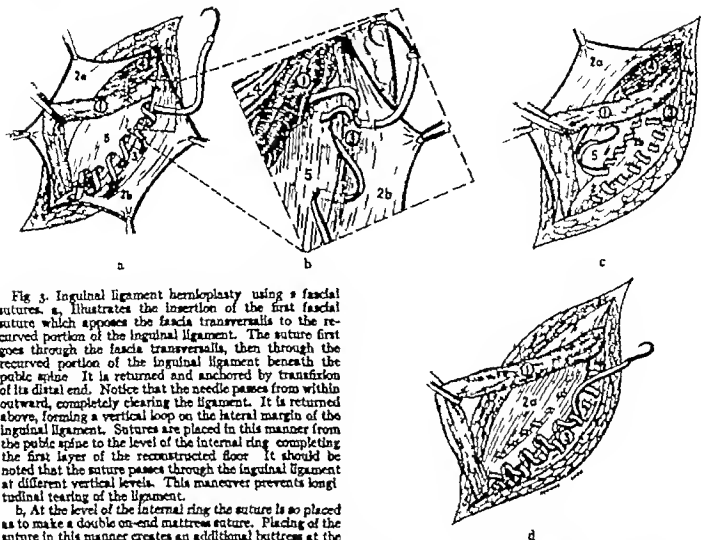

Fig 3. Inginal ligament hernioplasty using a fascial suture. a, Illustrates the insertion of the first fascial suture which apposes the fascia transversalis to the recurved portion of the inguinal ligament. The suture first goes through the fascia transversalis, then through the recurved portion of the inguinal ligament beneath the pubic spine. It is returned and anchored by transfixion of its distal end. Notice that the needle passes from within outward, completely clearing the ligament. It is returned above, forming a vertical loop on the lateral margin of the inguinal ligament. Sutures are placed in this manner from the pubic spine to the level of the internal ring, completing the first layer of the reconstructed floor. It should be noted that the suture passes through the inguinal ligament at different vertical levels. This maneuver prevents longitudinal tearing of the ligament.

b, At the level of the internal ring the suture is so placed as to make a double on-end mattress suture. Placing of the suture in this manner creates an additional buttress at the inferior margin of the internal ring, a potentially vulnerable point in the floor. This feature in the placement of the suture at the internal ring is of greater significance when there is extra aponeurotic funicular displacement because in this arrangement the external and internal rings actually superimpose. This is done by reversing the transversalis bite. The needle is passed lateral to medial and moving on to the middle of the lateral aponeurotic flap at the same vertical level. This maneuver also pulls the lateral flap medially.

c, The suture is then continued, imbricating the lateral flap to the anterior surface of the fascia transversalis or rectus sheath. This completes the use of the first fascial suture and forms the second layer of the floor.

d, The medial aponeurotic flap is sutured over the lateral with the second fascial suture. The suture begins at the pubic spine and continues laterally to the level of the inter-

nal ring. This imbrication forms the third fascial layer of the floor. Notice this suture passes through the loops previously formed on the lateral margin of the inguinal ligament by the first fascial suture. This step is important as it obviates the necessity of the suture going through the inguinal ligament a second time. Consequently trauma to the ligament is minimized. This technical feature in the placement of the fascial suture has not been previously emphasized insofar as we have been able to determine in our review of the literature. The cord is now placed extra-aponeurotically. Beneath the cord there are three reinforcing fascial layers, held by two fascial sutures, an all-fascial closure.

1, Spermatocord 2a, medial flap external aponeurosis 2b lateral flap, external aponeurosis 3 inguinal ligament 4 internal oblique muscle 5 transversalis fascia.

is a bolder more aggressive attempt to overcome the manifold structural deficiencies or weaknesses that occur incidental to the progressive development of large hernias. It comprehends the use of fascial sutures, muscle, fascial or cutis grafts. If the donor structure is one of the strata in the operative field as in the McArthur technique in which a strip of external oblique aponeurosis is used as a suture, no additional skin incision is

required. However if the donor structure is remote to the inguina, it will necessitate the introduction of another usually small incision. The Gallie sutures from the fascia lata, the plantaris tendon of Pilcher, the Kirschner patch graft, and the Wangenstein pedicle graft are notable examples. This advance step of fascioplasty in the reconstructive repair of hernias opened up a broad field for the exercise of ingenuity on the part of

the surgeon in the selection and physiologic application of identical histologic or generically closely related tissues.

Therefore with this newly acquired phase of structural substitution it should be no surprise that the past quarter of a century has witnessed an unending procession of plastic maneuvers, all designed for the ultimate correction or cure of inguinal hernia.

Coincident with the development of the various plastic maneuvers, the idea of deeper anchorage of the parietal wall to the iliopectineal (Cooper's) ligament was revived. This basic departure in technique in which the inguinal and iliopectineal ligaments are placed in additive and at times, competing roles, has resulted in the classification of hernioplasty as (1) inguinal ligament hernioplasty and (2) iliopectineal ligament hernioplasty.

INGUINAL LIGAMENT HERNIOPLASTY

Because of its accessibility and almost unvarying density, the inguinal ligament has long been employed for anchorage of the medial fascial boundary. For many years it was the only ligament used in hernia repair. So long as it retains its integrity there is no valid reason for altering this procedure, notwithstanding some recent changes in anatomical concept particularly in regard to the insertion of the fascia transversalis and internal oblique muscle. Herniorrhaphy presupposes a relaxed in contrast to a deficient floor but to slavishly follow this technique in all hernias and at the same time to neglect any indicated mural revision is illogical and will result in some avoidable recurrence. Consequently in those hernias presenting concomitant fascial deficiency of the floor of the canal, it is essential that the fascial stratum be replaced or reinforced before its ligamentous apposition. This should not imply that the antecedent removal of the peritoneal sac and definition of fascio-aponeurotic structures are not of foundational importance but it is intended to emphasize the value of the complementary plastic phase of the repair. The suitability and accessibility of like or generically related tissues forms the basis for the various technical departures and has led to the classification of inguinal ligament hernioplasty into (a) fascial sutures, (b) fascial grafts, (c) muscle grafts, and (d) cutis grafts. Heterogeneous sutures are excluded from consideration as not properly falling within the scope of this discussion.

Fascial sutures. The earliest and simplest departure from the conventional technique was the employment of a pedicled fascial suture, which was taken from the mesal cut edge of the external

aponeurosis but was left attached to the pubic spine. It was used as a running suture apposing the fascia transversalis to the inguinal ligament. This autogenous suture technique was devised by McArthur in 1901 almost a half century ago. Similarly double sutures from the same donor site have been employed by Robins, Sachs, Bigard, Gaston and others. The technique was modified by Hodgkins, Le transverse raised pedicled strips of the rectus sheath are passed successively through the base of the medial aponeurotic flap, the adjacent fascial boundary of the canal, and the recurved portion of the inguinal ligament.

The pedicled suture possesses the advantage of not requiring an additional incision. Its disadvantages are the McArthur suture is relatively short and because of this will not permit darning or weaving a coexisting defect in the floor. Should the patient have a narrow external aponeurosis, it would shorten the suture proportionately with the result that it might not be long enough to reach the internal ring. The preparation and placement of the multiple interrupted sutures of Hodgkins are time-consuming and create considerable trauma.

The free fascia lata suture of Gallie and Le Mesurier is the most widely used autogenous suture. In the experience of many surgeons, Garner, Joyce, Mason, Masterson, Wangensteen, Burton and Ramos, it has resulted in the lowest recurrence rate in the group of recurrent or difficult hernias. The steps of the technique in the use of fascia lata sutures are illustrated in Figures 30, 31, 32 and 33. The insert shows the strategic maneuvers of the suture in implementing the wall at vulnerable points. The living fascia suture in hernia repair has not escaped its critics but the dissenters are few. Burdick, Gillespie, David and Higginbotham, and Grace and Johnson, have criticized the fascial suture technique because of a higher incidence of recurrence and infections in their series.

The plantaris tendon has been employed by Pilcher but only one suture is available from each leg, there is agenesis of the muscle in 7 per cent of individuals, and the tendon is inadequate in size or strength in an additional 9 per cent (Daseker and Anson) these are serious drawbacks to its procurement. The ability of the tendon to fan out and span the space between the sutures is a property not possessed by fascial sutures. The heterologous or fascia of Koontz, Glaser and Egan can be preserved. It is therefore easily available (and another incision is avoided) yet more irritating, which is an objectionable feature. Chandy has shown experimentally that or fascia

may not completely disintegrate for as long as 5 years in some instances but, despite this, ox fascia has never gained wide acceptance in hernia repair.

Fascial grafts. The three types of fascial grafts are pedicled, free and sliding. By reflecting the anterior rectus sheath lateralward and attaching it to the shelving portion of the inguinal ligament there is created an additional fascial stratum superimposing the canal. This hinged on-side pedicled graft was employed by Berger (1902), and by Halsted (39) (1903). Estes (1941) added another maneuver by suturing the lateral aponeurotic flap to the mesial cut edge of the rectus sheath. Small on-end grafts raised from the upper thigh subjacent to the inguinal region and pedicled near the inguinal ligament, have been described by Cowell (1927) and Turner (1933). Large on-end grafts of the iliotibial tract pedicled on the tensor fascia femoris muscle, have been employed by Ach (1910), Wangenstein (1932), Wilmoth (1937) and Burton and Ramos (1940). These large massive grafts are almost imperative where there exists a huge mural gap. The patch graft of Kirschner and of Singleton and Stebrower in

Fig. 4. Hernioplasty Iliopectineal ligament (Cooper's)
a. The important anatomical structures of the inferior inguinal triangle and their relationship to the iliopectineal ligament are illustrated.

b. The first step of the repair is the insertion of the deep or first fascial suture. It begins posterior to the pubic spine and is directed laterally through the fascia transversalis and the iliopectineal (Cooper's) ligament. The suture is autotransferred and then progresses through the same structures to the level of the iliofemoral vessels. Although easily accessible medially, Cooper's ligament is quite deeply placed laterally. Care must be taken in the placement of the deep sutures in this ligament to avoid puncture or trauma to the external iliac vessels. We insert the index finger which protects and displaces these vessels lateralward during the placement of the last suture in the ligament. This lateral junctional angle is a vulnerable area

and, in our experience, the most likely site of recurrence. It is therefore essential that the fascia transversalis be brought in contact with the major vessels in order to obliterate any chink. The suture is drawn taut, apposing the fascia transversalis to Cooper's ligament and incidentally excludes the femoral ring. A relief incision in the anterior rectus sheath as proposed by Fallis, Tanner and Rienhoff, may be necessary if there is undue tautness of the wall.

c. The suture is continued passing through the iliopectineal ligament, fascia transversalis and the inguinal ligament at the level of the iliofemoral vessels.

1, Spermatic cord 2, medial flap, external aponeurosis 3, inguinal ligament 4, internal oblique muscle, 5 transversalis fascia 6 iliopectineal ligament (Cooper's) 7 femoral ring 8 femoral artery and vein 9 obturator artery 10 rectus sheath incised

Fig. 5. Hernioplasty, Inguinal Ligament (continued)
 a. The suture continues through the medial parietal wall and the inguinal ligament to the internal oblique ring. The transition of the suture through different mural and ligamentous levels is strategically important for it bridges the very widest point of the vulnerable interligamentous space.

b. Another potential weakness of the all is inguinospermatheal or interligamentous space which should be obliterated. This is the purpose of the second fascial suture. This suture passes through the first loop of the previous fascial suture going upward and from within out and pierces the inferior margin of the inguinal ligament. It returns by forming a loop on the lateral margin of the ligament. The process is repeated through the succeeding loops of the first fascial suture to the level of the iliofemoral

c. The loop of entering the inguinal ligament to Cooper ligament as originally proposed by Roggi and later popularized by Moskowitz.

c. The placement of the second fascial suture through the loop of the first suture further trussing to the iliopectineal (Cooper) ligament. This suture when drawn taut spaces and obliterates the interligamentous space and simultaneously loses the femoral ring. It also makes the inguinal ligament taut thus precluding herniation between the inguinal and iliopectineal ligaments which further adds to the structural security of the all.

1. spermatic cord 2a. medial flap, external spermectomy; 2b. lateral flap, external spermectomy 3. inguinal ligament; 4. internal oblique muscle 5. transversalis fascia 6. iliopectineal ligament (Cooper) 7. femoral ring 8. rectus sheath incised.

which the fascia lata is the donor site, is easier to apply and less time-consuming but there is greater likelihood of its fibers tearing and the wall is less resistant.

A very valuable and simple maneuver and one gaining in favor has been described by Falls, and Tanner and Rlenhoff in which the rectus sheath is incised medially which allows separation of the fascia over the rectus fibers. In effect, it is a sliding fascial graft. Usually the relief incision will permit approximation of the cephalad fascial boundary of the canal to the shelf of the inguinal ligament without tension.

Muscle grafts Another ingenious variant to implement the abdominal wall defect was devised by Bloodgood and Wölfer. They fanned out the lateral and inferior rectus fibers and sutured them deeply to the inguinal ligament. Because of the abnormal directional pull on the fibers with each contraction they did not remain for long in their displaced position. This repair was unphysiological and was soon abandoned. DeGarny sectioned the sartorius muscle and used one end to plug the femoral ring. This technique, too, was not suc-

cessful. To one familiar with the fate of redundant tissues, it is hard to convince oneself that the tampon remains for years just as it was at operation and even if not entirely absorbed, it is at least greatly reduced in size.

Cutis grafts The latest plastic technique to be introduced in hernia repair is the dermal graft, which may be either full thickness, Thiersch, dermatome flap or split-split graft. Cannady and Mair report success with the use of transplanted dermal grafts nevertheless much skepticism exists regarding these grafts. During the patient's convalescence there is no support of the wall from this type of graft and potentially there is a greater likelihood of infection.

For the surgeon of limited experience and training in the repair of difficult hernias, and to add in the selective application of inguinal ligament hernioplasty the following criteria may serve as a guide: (a) large indirect hernias with loss of obliquity of the canal (b) all direct hernias (c) indirect-direct hernias associated with attenuation of the fascia transversalis (d) most sliding hernias.

Fig 6 Hernioplasty Iliopectineal ligament (continued) a. The remainder of the second fascial suture is returned, imbricating the lateral aponeurotic flap to the rectus sheath. By this imbrication the second fascial layer is formed. Up to this point in the progress of the repair fascia is apposed to fascia by fascia, creating a double layer parietal floor (Completion of second fascial suture) b. The medial flap is made to overlap the lateral. It is held in position by triple-O sutures which pass through the loop of the second autogenous suture. By planning the loops of the fascial suture and placing them with precision unnecessary trauma to the ligament is avoided. The cord is transposed extra-aponeurotically (Completion of fascial flap imbrication)

1 Spermatic cord 2a, external oblique aponeurosis, medial flap 2b lateral flap 3, inguinal ligament 4, internal oblique muscle

ILIOPECTINEAL LIGAMENT HERNIOPLASTY

In the presence of inadequacy of the inguinal ligament the surgeon is confronted with three alternatives (1) the substitution of the iliopectineal (Cooper's) ligament, (2) repair or stabilization of the inguinal ligament, and/or (3) its plastic reconstruction. The second and third procedures have largely been abandoned except as adjunctive procedures.

With the acceptance of the fundamental role of the iliopectineal ligament in certain types of anatomical weaknesses that occur in recurrent and difficult hernias, there have developed successively many corrective surgical procedures.

The three vulnerable areas which are constantly present and must be reckoned with in Cooper's ligament hernioplasty are (a) the femoral ring (b) the inguinopectineal or interligamentous space, and (c) the junctional space which is bounded by the iliopectineal ligament, iliofemoral vein, inguinal ligament, and medial edge of the parietal wall. The apex of this pyramidal space is located at the newly created external ring.

To overcome these potentially weak areas, iliopectineal hernioplasty may be divided into the following evolutionary technical variants (a) femoral hernioplasty (b) pectineal hernioplasty (c) inguinopectineal hernioplasty, and (d) combined inguinopectineal hernioplasty.

Femoral Hernioplasty Femoral herniation is simply a variant of the peritoneal sac which has made its exit through the femoral ring into the canal. Since the femoral ring is deep to the inguinal ligament, the usual inguinal ligament hernioplasty would not correct this hiatus. Formerly femoral hernias were approached from below the inguinal ligament; however by this route it is not possible to totally remove the sac or to explore it to determine the presence of other saccular variants. It was in this type of hernia that Cooper proposed using the ligament which he described and which is named after him. Annandale (1876) has the distinction of having been the first to employ Cooper's ligament in the closure of the femoral ring by the inguinal approach. Others who have made valuable contributions to this technique include Auchincloss, Carscadden, and Payne. The femoral ring may be obliterated by suturing the inferior margin of the inguinal ligament to Cooper's ligament provided the former is lax. Should the inguinal ligament be taut, the ring may be spanned by weaving a fascial suture between the two ligaments.

Pectineal hernioplasty Additional etiological factors which should be recognized in the effective closure of the inguinal floor are inadequacy of the inguinal ligament and preternatural laxity of the parietal wall. The inguinal ligament may be so

attenuated or friable from previous trauma or infection that only a few strands remain, which prevents its use as an effective barrier to intra-abdominal pressure. To correct this ligamentous insufficiency it is necessary to either repair the ligament or substitute another. Experience has shown that the latter is the more practical and effective procedure. The iliopectineal superior pubic or Cooper's ligament is a very dense constant structure intimately related to the superior pubic ramus which is deep to and somewhat medial to the inguinal ligament. The employment of Cooper's ligament in lieu of the inguinal ligament dates back to 1809 when Lothsen, while operating on a recurrent hernia, discovered that the inguinal ligament was destroyed and he was confronted with the necessity of finding a structure for mooring the wall. He successfully substituted the former and he repeated this procedure in a series of 12 cases. This innovation in hernia repair was lost sight of for two decades before its revival in America by Scellig and Tuholske, Dixon and McVay. As the criteria for repair with the use of Cooper's ligament have been more clearly defined the technique has steadily gained wider acceptance. Silk may be used but we prefer a living suture for apposing the wall. The latter provides a broader contacting surface between the wall and ligament and it acts as a living graft bridging the lateral vulnerable angle. Autogenous fascial sutures are nonirritating and survive as long as 5 years. Figure 4b illustrates the placement of this suture which is the first step in the repair.

Inguinopectineal hernioplasty. The largest vulnerable space of the inguina lies between the inguinal and iliopectineal ligaments. The inferior margin of the inguinal ligament has no structural support except for the small, medial lacunar ligament and a thin, poorly defined band of connective tissue of little retentive value lateral and superjacent to the iliofemoral vessels. Consequently the stability of the inguinal ligament depends almost exclusively on its tautness between its points of origin and insertion. Since the inguinal ligament is a continuation and reflection of the external aponeurosis it is subject to the same factors which predispose to weakness of the abdominal wall. Moreover it is conceivable that the greater the pull cephalad on the external aponeurosis, particularly if there is concomitant intrapelvic pressure, the greater the likelihood of widening of the interligamentous space. Consequently as vulnerability of the interligamentous space has become more evident attention has been focused on measures designed to reinforce or

exclude it, preferably the latter by altering the ellipsoidal contour of the floor of the inguina by attaching the medial fascial boundary to Cooper's ligament. Rugge (1898) first proposed obliteration of this space but this variant received scant attention until popularized by Moschowitz. Rugge and Moschowitz used silk which is very satisfactory if the ligaments can be apposed, but if the inguinal ligament is taut its use will simply result in the sutures cutting through the ligament, which will revert to its former position. The other alternative is the obliteration of this space by weaving a living fascial suture between the two ligaments which not only affords stability but serves as a graft by spanning this space (Fig. 5b). It should be recalled that Moschowitz envisaged this technical step of pectinealizing the inguinal ligament which he introduced as adjunctive to inguinal ligament hernioplasty and not as we think of it presently as one of the departures of Cooper's ligament repair.

Combined inguinopectineal hernioplasty. The preceding modifications in technique in the use of Cooper's ligament which are described, are all progressive steps and each step was designed to reinforce or exclude an anatomical weakness—muscular, ligamentous or interligamentous—so, it is only logical in our quest for a better operation, to project a composite technique which would embody the important surgical features of each into one integrated procedure. For instance in the first technical variant attention was focused on removal of the sac and closure of the femoral ring; in the second, the interligamentous space and femoral ring were excluded; the third was primarily the closure of the interligamentous space and the fourth, as the name implies, is a combination of the pectineal and inguinopectineal variants into one integrated procedure by employing two fascial sutures. The first fascial suture anchors the pectineal wall to the iliopectineal ligament and continues lateralward and upward from the transitional angle apposing the wall to the inguinal ligament (Fig. 4c). To further implement the wall a second fascial suture bridges the space between the inguinal and iliopectineal ligaments (Fig. 5b). While the latter may not always be essential in the prevention of a recurrence it certainly augments the inguinal ligament and provides the ultimate in preventing the development of minute or potential weaknesses. The details of the combined technique are described more fully with the illustrations. With increasing experience in the repair of Cooper's ligament we find ourselves using the composite procedure almost to the exclusion of the other variants.

The criteria which should be present before considering repair of the iliopectineal (Cooper's) ligament are

- | | |
|---|-----------------------|
| (a) All femoral loculations of the sac | absolute indications |
| (b) Inadequacy of the inguinal ligament | |
| (c) Arborescence of the sac | equivocal indications |
| (d) Generalized laxity of the inguinal wall | |
| (e) Widening interligamentous space | |
| (f) Refractory hernias | |

SUMMARY

1 A classification of hernial operations based upon evolutionary phases of their development in keeping with the modern concept of hernia repair has been presented

2 The criteria for each basic repair have been outlined

3 The anatomically weak areas, the medial angle of the floor and the internal ring in the superior inguinal region and the femoral ring interligamentous space and the lateral transitional or junctional angle in the inferior inguinal triangle, have been correlated in the application of the various techniques

4. The inguinal ligament repair has been contrasted with the iliopectineal ligament three-dimensional repair

5 The vulnerability of the inguinopectineal (interligamentous) space has been emphasized with proposal of technical maneuvers for its reinforcement or exclusion

6 We concur in the previously expressed opinion of Falis that the real cause of recurrence lies in a technical error at the primary operation, for if the factors predisposing to recurrence had been recognized then and adequate steps taken to circumvent them the first operation would have been as satisfactory as the last.

selection on entering the industry and even if this was possible it would seem unwise to exclude from the mines a body of men who would give many years of satisfactory service before breakdown.

JAMES E. LERENSON, M.D.

Binocular Vision in Miners. DOROTHY ADAMS CAMPBELL, RENE HARRISON, and JEAN VERTIGER. *Brit J Ophth* 1948 3 6

The binocular vision of miners with nystagmus was compared to that in other coal miners and in normal controls in the various age groups. Each subject was tested for stereoscopic vision, fusion, duction and simultaneous perception in both light and dark adaptation. In all of the eyes examined the subject's angle tended to become convergent when dark adapted but this response was less in those with miners' nystagmus. The majority of miners fixated abnormally with the eyes looking somewhat upwards.

An incidence of about 10 per cent poor stereoscopic vision occurred in the controls, and tended to increase with age and under dark adaptation. This variation was greater in miners and most marked those suffering from nystagmus. The power of adduction in the control subjects did not vary with illumination or with their stereoscopic efficiency but in all the miners with good stereoscopic vision adduction was overdeveloped and in those with poor stereoscopic vision adduction was almost nil.

A breakdown in binocular vision occurs under conditions of low illumination. In the early stages of miners' nystagmus the nystagmus is usually vertical and may be unilateral. In the intermediate stage of bilateral nystagmus, any attempt at macula fixation results in macular suppression, though some degree of fusion, duction and stereoscopic vision is present. In cases of long standing in patients who have been off work for a long period no nystagmus can be elicited, but the outstanding features—photophobia, blepharospasm, and psychoneurosis—prevent any evaluation of binocular function at this stage.

JAMES E. LERENSON, M.D.

Preglaucoma. SANDERS K. STROUD. *Trans J M* 1948, 43, 690.

This article deals with a syndrome called preglaucoma which is a difficult condition to diagnose because of its vague and elusive subjective symptoms and objective findings.

The subjective symptoms are (1) mild or severe headaches, occipital, ocular and down the neck, the pain usually being worse at night (2) drowsiness to a pathological degree (3) lacrimation (4) discomfort with refractive correction and (5) decreased accommodation.

These symptoms were found in any age group, with any type of refraction, in all races, and in all physical types.

Objective findings are almost absent and tension is normal. Frequently the eyes are irritable and become inflamed on manipulation. Vision may be

slightly below normal. The visual fields are normal but there may be a slight enlargement of the blind spot. Repeated tonometer readings may show a slight difference of from 5 to 10 points between the two eyes. Also the variation of tension before and after (a) the administration of mydriatics, (b) a visit to the movie theater (c) coffee drinking, should be observed as well as morning and evening variation. Any variation of five points is suggestive. Any of the above findings should lead to a therapeutic test of mild miotics which should relieve symptoms.

The relationship of this condition to glaucoma is not clear. Many patients never develop glaucoma even without treatment, and of those who do, some develop the acute uncompensated form and others the chronic compensated variety.

EARL H. MEHL, M.D.

Glaucoma following Cataract Extraction. WILLIAM COCKLEMAN OWENS. *South M J* 1948, 4, 157.

This article deals with the postoperative occurrence of glaucoma in 2,086 cataract extractions at Wilmer Institute during the period between 1925 and 1943.

In this group the overall incidence of postoperative glaucoma, including all methods of cataract extraction was 4.2 per cent. The incidence of glaucoma in the group of intracapsular extractions with corneal sutures in patients with normal pupils was 6 per cent.

Glaucoma following cataract extraction is almost always secondary to some complication that has or is occurring during the course of the operation. The complications that most frequently predispose to secondary glaucoma are (1) postoperative iridocyclitis resulting from retention of lens material or loss of vitreous (2) poor closure of the wound with delayed or nonreformation of the anterior chamber (3) incarceration of iris vitreous, or capsular material in the incision (4) epithelial downgrowth (5) inadequate communication between the posterior and the anterior chamber.

These complications are the predecessors of postoperative glaucoma and can usually be avoided by certain operative techniques. The operation should be performed under adequate anesthesia. The speculum should cause no pressure on the globe. A conjunctival flap and corneoscleral sutures should be used to promote firm closure of the wound and rapid formation of the anterior chamber. A round pupil should be preserved but an adequate peripheral iridectomy or iridectomy should be made. The lens should be removed in its capsule if possible but if the capsule ruptures, the eye should be cleared of as much lens material as possible. Lastly the wound should be carefully inspected and freed of any incarcerated vitreous, capsule or iris tissue.

The treatment of this type of glaucoma varies with the condition. If tension is due to iridocyclitis it is best to use mydriatics and nonspecific protein therapy. If a sensitivity to lens protein can be demonstrated, desensitization is in order. If surgery

must be resorted to in the presence of active indocyclitis in an aphakic eye a corneoscleral trephine is the operation of choice

In most cases all signs of active indocyclitis have disappeared before tension becomes elevated. In these myotics are used

In cases of mechanical block between posterior and anterior chamber a transfixation operation will prove of value.

When the anterior chamber angle is blocked a cyclodialysis is the operation of choice

EARL H. MERR, M.D.

Orbital Restoration with Buccal Mucosa JAMES N. GREER, JR. *Am J Ophth* 1948 31 445

The author introduces the subject of orbital restoration with buccal mucosa by reviewing the attempts at socket restoration in early days. The first world war gave great impetus to this procedure and World War II with its orbital injuries has provided ample opportunity for further study

Mucous membrane of the mouth was used because it is easily accessible clean free from odor and its removal leaves no residual deformity at the donor site. There is sufficient mucous membrane in the mouth for complete restoration of the orbit. The procedure is outlined as follows

Preoperative procedure The operative field must be free from infection and well healed.

Anesthesia. Either local or general anesthesia is satisfactory. If general anesthesia is decided upon intratracheal intubation is used

Preparation The area is well cleansed with soap and water and a 1 to 5000 aqueous solution of sephiran on gauze is used as a mouth pack. The pack remains until dissection of the socket is completed.

Preparation of the bed to receive the graft is carried out according to Wheeler's technique. The plane of dissection is superficial, the dissection is carried to a point beyond the orbital margin—below and temporally. Nasally it extends to the anterior crest of the lacrimal groove and to the orbital margin beyond. The caruncle must be preserved if possible. Bleeding must be completely controlled. All scar tissue and granulation tissue must be excised

The graft is removed from the buccal surface after infiltration of 1 per cent novocaine and Stenson's duct must be preserved. Trauma must be minimal. All submucous tissue is then excised from the graft. The buccal wound is closed with mattress sutures and the buccal wound is sutured into its new bed of heavy silk. The graft is sutured into its new bed with interrupted No. 6-0 black silk sutures. Three or four 4-0 sutures are threaded through rubber tubing and through the graft in depth of new fornix and are passed through periosteum above and below to anchor them. The socket is then packed with ¼ inch vaseline gauze.

Postoperative procedure The first dressing is allowed to remain for 5 to 7 days, and firm packing is applied then dressings are changed every 3 days for 2 weeks or until the graft is well healed

EARL H. MERR, M.D.

Management of the Wound behind the Ear following Mastoidectomy (Behandlung der Wunde hinter dem Ohr nach Aufmei3elung des Warzenfortsatzes—Mastoidektomie) TH. HUBERDMANN *Dtsch. med. Wochschr* 1948 73 18.

The author traces the evolution of management of the wound behind the ear following mastoidectomy. Formerly the antrotomy wound was left wide open and packed with a tamponade which was changed frequently. Wound healing was painful, required 6 to 8 weeks and resulted in a deep depressed scar. Attempts at primary suture were often followed by dangerous complications. Partial closure with iodoform gauze drainage strips and compression dressings shortened the healing time.

The author believes that scar abscesses and retroauricular fistulas are results of an incomplete operation. His experiences with primary suture have led to the following conclusions

This is the method of choice when used in conjunction with sulfonamides for primary closure is careful and complete removal of all cells. The wound cavity should be filled with sulfonamide powder and in the first 3 days after operation sulfathiazole should be administered. The desirability of the method lies in the shortening and simplifying of the postoperative care and the freedom from pain during the healing period. JOHN L. LINQUIST, M.D.

The Fenestration Operation A Survey of 500 Cases. HOWARD P. HOUZE, *Ann. Otol. Rhinol.*, 1948, 57 41

The author gives a survey of 500 fenestration operations for otosclerosis, all of which were done more than 6 months previously and attempts to answer from the results obtained three questions which the patient asks regarding the operation. These questions are:

1. Am I a suitable subject for surgery?
2. What are the possible complications of such a procedure?
3. What results may I expect following the fenestration operation?

The author gives a brief discussion of the operation and postoperative care. He uses a slight modification of the original Lempert novovalis technique. The cartilage stopple, the gold burr and the more recent lead burr technique were not used in this group.

Indications for fenestration surgery. A patient with a progressive conduction type of hearing loss with intact ear drums and patent eustachian tubes is suitable for operation provided he does not have serviceable hearing, his general health must be good, and he should have good cochlear nerve function. Previous ear infection or even mastoid surgery does not contraindicate fenestration provided the ear drum is intact.

Patients more than 60 years of age should rarely be operated on. If such patients have good nerve

function they will hear well with a hearing aid for the remainder of their lives.

The determination of cochlear nerve function is very unsatisfactory and better methods of determining this function will have to be developed. However, determinations made with bone conduction audiograms and tuning forks have been reasonably effective.

The author divides the patients into three classes:

1. In the ideal case the cochlear nerve loss does not exceed 20 decibels in the speech frequencies.

2. In the borderline case the cochlear nerve loss must not exceed 20 decibels in the 512 and 1,024 frequencies, and must not be greater than 30 decibels at the 2,048 level.

3. Any patient having a cochlear nerve loss below the borderline group is generally considered to be nonsuitable for surgery.

Rarely however one is justified in operating on a so-called nonsuitable case, particularly that of a young individual with a rapid loss of both air and cochlear nerve function as the operation at times will prevent further nerve deterioration.

The poorer ear is usually selected for operation but in some cases the patient has found out that the hearing aid is more effective in the poorer ear and then the operation may be advisable on the better ear. Often, if tinnitus is less noticeable in the poorer ear it may be advisable to operate on the better one. With normal hearing in one ear there is no justification for operation on the opposite otosclerotic ear. It may be justified in rare cases in which unbearable tinnitus is present in the otosclerotic ear.

Surgery is not contraindicated during early pregnancy if the patient with otosclerosis gives a history of hearing loss during a previous pregnancy. An operation then may have a chance of preventing further hearing loss. The advisability of terminating pregnancy arises in patients with otosclerosis exhibiting a marked cochlear nerve loss, which is not suitable for operation. The ultimate decision must rest with the patient.

Aural discharge was bothersome in some 20 per cent of the cases. This drainage may be intermittent or continuous and at times becomes secondarily infected. This complication has become less frequent in patients more recently operated on because of the technique of creating a smaller mastoid cavity which allows epithelialization to occur more rapidly.

Results obtained by fenestration. Eighty-five per cent of the 500 patients in this series complained of preoperative tinnitus. 34 per cent of these were completely relieved and an additional 54 per cent were partially relieved of this complaint.

The improvement in hearing is shown in the following table:

HEARING RESULTS OF ALL OPERATED CASES

	N	%
Serviceable hearing	357	70+
Improved hearing but non-serviceable	86	17
Unchanged	44	9
Closure of fenestra	39	8
Air conduction worse than preoperatively	9	4
Bone conduction worse than preoperatively	5	

In this series of 500 cases, 8 per cent of the patients lost their initial hearing gain because of closure of the fenestra within the first 6 months. An additional 3 per cent closed during the second 6 months. To date the author has observed no closure in any patient after the first year. Therefore, after one year more than 66 per cent of all patients in this series have maintained serviceable hearing.

Closure of the fenestra usually occurs the third or fourth month following surgery. When closure occurs in one ear, it does not indicate that closure would occur in the opposite ear also if that ear were operated on. The second ear should not be operated on if the hearing did not reach the serviceable level in the first ear immediately following the operation, unless the patient is able to hear well in the ear originally operated upon.

SURGERY OF THE HEAD AND NECK

microscopic findings. With proper treatment the prognosis is excellent.

In the present series the lesion occurred chiefly in the aged the average age being 67 years. Tobacco chewing was thought to be a most important etiologic factor. The predominant sites of the lesion were on the buccal mucosa and lower gingiva a tendency to invade contiguous structures was the rule but no evidence of distant metastasis was found in any of the 31 patients whose cases were studied. Local metastasis too was rare although the concomitant infection frequently caused enlargement and tenderness of the regional lymph nodes which often leads to an erroneous diagnosis of metastatic carcinoma on an erroneous diagnosis of metastatic carcinoma.

Grossly the papillary lesions present a somewhat pebbly mammillated surface pitted up in rugal folds with deep cleftlike spaces between them. Microscopically the lesion begins with a piling up of keratin on the surface and a beginning downgrowth of fingers of epithelium. With progression, club-shaped fingers of a hyperplastic, well differentiated epithelium with an intact basement membrane eventually push their way into the deeper tissues, eventually producing deep cleftlike spaces of degenerating keratin and cystic degeneration of the deep central portion of the fingers. Beyond the progressing lesion is a wall of inflammatory tissue.

In the treatment of verrucous carcinoma of the oral cavity the treatment of choice depends on the extent of the lesion. For small superficial lesions it is believed that roentgen irradiation is apparently successful. Seven patients were so treated with recurrence in only 1 patient after a period of 43 months 4 others are living without recurrence after periods varying from 41 to 86 months. Two patients in this group died of intercurrent infection.

Seven other patients also received radiation therapy which was followed by surgical excision of the recurrence. Of these 3 have died of other diseases and 4 are living without further recurrence after periods varying from 6 to 60 months.

Local excision alone was the method of choice in 9 cases. One patient in this group died of intercurrent disease and one had a recurrence after 24 months. The rest are living without recurrence after periods varying from 4 to 36 months.

In 8 cases, excision plus mandibular resection and upper neck dissection was performed as the primary treatment. There was no recurrence in 7 patients after periods varying from 14 to 49 months one patient died of intercurrent disease.

In summary of 14 patients treated by irradiation, 8 had recurrences whereas of 17 patients treated primarily by surgery only 1 had a recurrence.

EUGENE L. DIERLACKI, M.D.

PHARYNX

The Pediatric Approach to Tonsillectomy J. ALBROW
GLOVER. *Arch. Dis. Child.*, Lond. 1948 23 2

The author states that in England and Wales the incidence of tonsillectomies in the last 45 to 50 years

has mounted from almost 0 to some 200,000 a year. Tonsillectomies are done more than three times as frequently among the children of the well-to-do as among the children who attend public elementary schools and varied from 0.1 to 5.0 per cent among all children in average attendance at the public schools from 1936 to 1938 in 19 Kent educational areas. The highest incidence occurs between the ages of 5 and 7 years with a peak at the age of 6. If the tonsil has a function of absorbing small numbers of organisms and so establishing immunity, by gradual dosage (Griffith, 1937) this is the time when it is most likely to be useful and when enlargement might be expected and might even be beneficial.

The indications for tonsillectomy are divided into two groups the objective based on the size and appearance of the tonsils, and the indirect for the prophylactic and curative effect of the operation. The author believes that physicians do not consider size alone as of clinical importance unless true obstruction occurs. However great difference of opinion exists as to the appearance of infected tonsils and removal on the basis of appearance offers a difficult decision. It is obvious that when the probable purpose of the intervention is to arrest the invading organisms the tonsil must be infected.

The author believes that frequently repeated attacks of acute tonsillitis, recurrent quinsy, or both are the most reliable indirect indications for tonsillectomy. He regards frequent colds as a symptom of sinusitis rather than as an indication for tonsillectomy and believes that sinusitis is a cause of tonsillitis. He believes that medically "bronchitis" is considered a contraindication to tonsillectomy and states that no beneficial effect on asthma and allergic states has resulted from tonsillectomy. Medical opinion is divided as to whether enlarged cervical glands constitute a proper indication but no conclusive evidence to date has been found to indicate that tonsillectomy greatly lowers the incidence of otitis media. Nephritis which in the past has been considered one of the more important indications for the removal of diseased tonsils, does not, in the author's opinion, constitute an adequate indication. He holds the same opinion with regard to acute rheumatism and carditis.

He believes the operation is never urgent and should be preceded by a period of observation of 6 months, after the completion of any necessary treatment of the teeth and sinuses.

JOHN J. BALLINGER, M.D.

NECK

Propylthiouracil: Its Use in the Preoperative Treatment of Severe and Complicated Hyperthyroidism. ELMER C. BARTELS. *West J. Surg.* 1948 56 226.

The author presents a series of 300 patients with moderate to severe hyperthyroidism treated with propylthiouracil. Propylthiouracil was found uniformly effective in reducing the basal metabolic rate.

when given in the daily dose of 500 mgm. for primary hyperthyroidism and 300 mgm. for adenomatous goiter with hyperthyroidism.

Toxic manifestations occurred in 6 cases. One of these had a fever reaction, 5 had depressive changes in the white blood cells, and one had agranulocytosis.

The author now combines Lugol's solution with propylthiouracil from the beginning of treatment in cases of primary hyperthyroidism, because he thinks the quick action of Lugol's solution produces more prompt subjective improvement although it does produce some delay in return of the basal rate to normal. No death occurred in the series following thyroidectomy. W. FOSTER MONTGOMERY, M.D.

Studies on Thyrotoxicosis. JAMES HENRI. *West. J. Surg.* 94, 56-59.

The author classifies thyrotoxicosis as primary and secondary. The primary types comprise the forms due to hyperplastic processes in the gland, namely exophthalmic goiter and conglomerate goiter. The secondary types of thyrotoxicosis comprise those occurring in a gland not otherwise thyrotoxic. This includes neoplastic processes, adenomas, papilliferous tumors and carcinomas, further inflammatory processes, and thyrotoxicoses induced by iodine or roentgen treatment.

With regard to the pathological picture of thyrotoxicosis, the author classifies the microfollicular mass proliferation of epithelium as type 1 and the macrofollicular proliferation with the big winding follicles and the papilliferous excrescences as type 2.

Cardiovascular symptoms, circulatory dynamics, and the preoperative treatment are discussed.

It is believed that the importance of radical operation cannot be overestimated. A table is presented

to show the serious risk that is involved in the reoperation. W. FOSTER MONTGOMERY, M.D.

Malignant Tumors of the Thyroid Gland. BARTON McSWAIN and WALTER DIXELEY. *Surgery* 94, 175-5.

The authors report a small series, 23 cases, of malignant tumors of the thyroid gland in order to point out the fact that such lesions are uncommon in general hospitals outside of the goiter belt and to emphasize some points in their clinical manifestations, microscopic characteristics, and treatment. The authors place the tumors in their series in one of seven classifications: (1) papillary adenocarcinoma, (2) adenocarcinoma, (3) alveolar adenocarcinoma, (4) alveolar carcinoma, (5) giant-cell carcinoma, (6) squamous-cell carcinoma, and (7) sarcoma. Representative photomicrographs are shown.

The authors determined by their physical examinations that thyroid cancers could be soft, not all being hard in consistency. They think that microscopic observation of tumor cells in the blood vessels is not necessary for a diagnosis of carcinoma of the thyroid gland and is not always a reliable criterion of malignancy.

Carcinoma of the thyroid so extensive as to preclude operation other than biopsy should not be considered hopeless inasmuch as a patient with such a condition was reported to be alive without recurrence 8 years after diagnosis and treatment with roentgen rays.

The authors believe that recurrent malignant nodules should be removed.

One case of hypothyroidism present in a patient with carcinoma of the thyroid is presented.

W. FOSTER MONTGOMERY, M.D.

SURGERY OF THE NERVOUS SYSTEM

BRAIN AND ITS COVERINGS CRANIAL NERVES

Functions of the Frontal Lobes. W. RITCHIE RUSSELL. *Lancet* Lond., 1948, 1: 356.

As far back as 1878 Ferrier in England wrote that the removal of the frontal lobes causes no motor paralysis or other evident physiological effects but causes a form of mental degradation. Fulton (1943) writes that the types of deficit observed after removal of the frontal lobes relates to alterations in behavior—to intellectual deficits.

There is still some disagreement whether removal of one or both prefrontal lobes necessarily causes much change in intelligence or personality but no one will dispute that the so-called frontal lobe syndrome occurs. The famous American crowbar case of nearly a century ago is cited by the author and provides a remarkable record of bilateral frontal lobe injury.

In the experimental field progress has also been limited. Ferrier 75 years ago found that bilateral removal of the prefrontal area in monkeys caused considerable psychological alteration in their behavior. Jacobsen's (1934) observations on the effect of prefrontal lobectomy in experimental neurosis were of exceptional importance, for he clearly showed that the behavior of a chimpanzee with neurosis and temper tantrums was completely altered by the operation. The neurosis was cured at the expense of losing some ability to solve problems. This led to the application by Moniz (1936) of the operation of frontal lobotomy in man which is now so widely practiced.

Two facts stand out clearly: (1) there is little difference between the effects of removing the right or the left prefrontal lobe and (2) the removal of both prefrontal lobes causes more intellectual deficit than does the removal of one only. It also seems clear that the effect of removal varies from case to case as was shown by the studies of Moniz and others in Germany on frontal wounds after the war of 1914 to 1918.

An evaluation of frontal brain wounds in the late war disclosed that in most frontal lobe wounds fair recovery takes place. Of 75 unselected patients who have recovered from a frontal brain wound 66 (88%) are in some form of employment 2 years after wounding although the employment is often of a simple kind. There is often evidence of some change of personality and intellectual deficit. This is sometimes difficult to demonstrate by psychometric tests, and often the evidence provided by an intelligent patient or by his relations gives the best indication of his disability. Common symptoms are restlessness, inability to maintain attention or to plan, lack of self control, difficulty in learning, failure at technical or professional occupations, loss of interest in former hobbies or games, tactlessness, fatigability and more rarely nocturnal enuresis.

The author then discusses the effects of frontal lobe injury on emotional reactions and memory. The pattern of adult human behavior must depend to a large extent on memory and it is clear from studies of both frontal wounds and of frontal-lobe operations that the processes of memory are not centered chiefly in the frontal region. It seems evident that the removal of neither the whole right hemisphere (the left being dominant) nor both prefrontal lobes leads constantly to gross loss of established memories or alteration of behavior or intelligence in the adult.

There is some evidence to show that the mental effect of brain disease in children differs from that in adults. For example, it is well known that severe head injury or encephalitis in small children may lead to persistent disorders of behavior and arrest of mental development. It is, however, not known whether injury to the frontal lobes plays an important part in this clinical picture. Some evidence of the importance of the frontal lobes in the development of intelligence in childhood is provided by the association of dementia with atrophy or arrest of development of the frontal lobes (Bolton 1914).

Both the study of frontal wounds and the effects of frontal lobotomy in the adult indicate that the basic pattern of behavior is not represented in the frontal lobes yet this frontal mechanism may possess the power to exert a decisive influence in controlling the main behavior patterns which seem as has been mentioned to be established in the posterior parieto-temporal region of the dominant hemisphere. The study of children who have had severe frontal lesions suggests not only that their behavior is disinhibited and as one teacher remarked "he behaves like a monkey, but also that they cannot be educated. The study of patients with frontal lobe damage suggests that a loss of ambition and drive plays a part in their general ineffectiveness in the rush of modern life. The same incentives to succeed in life remain, but these do not elaborate the ambition necessary to provide for sustained and efficient mental and physical activity.

It seems that the beneficial effect of prefrontal lobotomy in relieving mental tension and severe anxiety may act in one of three ways: the operation prevents the relay of the nervous activities engendered by mental conflict to the fronto-hypothalamic mechanism; the fire of the mental conflict loses its fuel when no longer stimulated by this mechanism; or most likely the mechanism of mental conflict at a cortical level is highly complex and may be directly interfered with by this operation to such an extent that it can no longer develop the intensity required to stimulate the emotions. However, it is not yet possible to say which of these alternatives is the most important.

In conclusion the author states that the time is now ripe for investigation of the psychic results of

injury to different parts of the frontal lobes and that the evidence suggests that we have all used our prefrontal lobes to a great extent in the past to build up our own peculiar way of thought and life and to exploit our emotional capacity to provide the necessary drive to work. Most of us can still use them to enable us to work long hours to change our habit

and to plan along untried paths. In our later years it is easier to travel on the well worn paths of thought and behavior so if our mental conflicts become intolerable we may then gain something by having our prefrontal lobes destroyed.

HOWARD H. LASTER, M D

Pain Mechanisms and the Frontal Lobes: A Study of Prefrontal Lobectomy for Intractable Pain

WALTER FREEMAN and JAMES W. WATTS. *Ann Int Med* 9:18, 28 1947

Despite the widespread interest in the relief of pain by prefrontal lobectomy there has been a gross lack of understanding of its mechanisms. The short dissertation presented by these authors should help to dispel many of the vagaries associated with this problem. Although philosophers have argued in the past as to whether pain is a sensation or an emotion, the authors have elucidated this problem quite clearly by showing that the somatic quantitative recognition of pain stimuli is not interfered with in prefrontal lobectomy. However the emotional components of pain and emotional threshold are greatly influenced by this procedure. This is most clearly presented by the authors own words "Prefrontal lobectomy has a beneficent action upon pain whether it is primarily mental or primarily physical. It does not interfere with the perception of pain but rather with the evaluation of pain. It does not relieve pain but rather the disabling reaction to pain, the fear of pain. It does so apparently by eliminating the emotional component arising from the thalamus."

Although definite indications for prefrontal lobectomy in the relief of pain are not yet fully evaluated, it is thought to be a very valuable procedure in cases of pain in which suffering produces marked disability and in which the outlook for improvement under other measures appears very unsatisfactory. The authors believe that the procedure should be used more often in the relief of severe pain.

JACK I. WOOLF, M D

Hydrocephalus, and Hydrocephalus with Meningocele: Their Treatment by Choroid Plexectomy

LEO M. DAVIDOFF. *Surg Clin N America*, 9:18, 28 4 6.

This article is a plea for removal of the choroid plexus in the properly chosen patient with hydrocephalus, now that better and safer operative techniques are at hand. A brief but interesting review of the more authoritative opinions on the physiology of the cerebrospinal fluid is given. Obviously, be the fluid an excretion or secretion, anything which interferes with its free circulation (as obstruction of its pathways) or its prompt absorption (as impair-

ment of function of the arachnoid villi) will result in an accumulation of the fluid under pressure.

Following a brief critique of Dandy's operation of third ventriculostomy the author reports that he has operated upon 32 babies by the choroid plexectomy procedure for the relief of hydrocephalus. The diagnosis was always confirmed by means of ventriculography or by ventricular catheterization. He does not feel it particularly necessary to determine or know whether or not the hydrocephalus is communicating or "noncommunicating." Nineteen patients were operated upon by bilateral plexectomy and 13 were operated upon on one side only. At the time of initial operation the ages of the patients varied from 5 weeks to 15 months. In 9 patients there was an associated meningocele and the operation of plexectomy is believed to aid in the treatment of that lesion when it also exists.

In preparation for the operation, the lower portion of the calvarium is supported in a plaster mold cast to support it at the time of ventricular drainage. Through a small temporoparieto-occipital flap the cortex is incised, the ventricle drained, and as much of the plexus coagulated (clipped and excised, if that seems feasible) as is possible. The ventricle is then filled with warm Ringer's solution freshly made.

Fourteen of the 32 patients are known to have died 7 immediately after operation or within a few days after operation. Some of the patients were obviously very poor surgical risks and death was not surprising with or without operation. Infection occurred in some patients when a meningocele was also present, the infection probably gaining access to the subarachnoid spaces from the meningocele rather than from the operative wound. In 3 of the 9 patients with associated meningocele the meningocele healed spontaneously, but in 4 of these patients the meningocele required surgical repair. Several case reports are appended to illustrate difficulties as well as success with this operation, one of the major neuro-surgical challenges.

JOHN MARTIN, M D

Focal Epilepsy: Correlation of the Pathologic and Radiologic Findings.

DONALD L. McRAE. *Radiology* 9:18, 50: 430.

In this article the author considers the verification of foci of brain pathology resulting in epilepsy as they are demonstrated by means of radiology and clinically by physical examination of the seizure itself, and operative verification. He has found that atrophic lesions of the brain in children are often associated with a smaller hemisphericum on the affected side, this disparity being shown by accurately made x-ray pictures of the skull. In the 160 patients studied from the Montreal Neurological Institute and Children's Memorial Hospital of Montreal, atrophic cerebral lesions were compared roentgenologically with meningocerebral electrical lesions. The common meningocerebral cicatrix was associated with focal ventricular dilatation in 80 per cent of the patients and with demonstrable subarachnoidal cysts in 28 per cent. There was also, a great incidence of

specific bone changes which the author has come to believe are characteristic of this sort of cerebral focus. In the second largest group of patients those with the simple forms of cerebral atrophy and in whom there was so frequently seen a cranial hemiatrophy bone changes other than hemiatrophy were relatively uncommon. focal ventricular dilatation was present only in 38 per cent of the patients and subarachnoidal cysts were present in only 5 per cent. In a third group of patients, 9 with blood vessel abnormalities, intracerebral calcification occurred in 44 per cent, an incidence 15 times greater than that in any other group. Among the patients with blood vessel abnormalities there were occasional instances in which an atrophic or actually a space-occupying lesion might have been suspected.

In 8 patients plain roentgenograms and pneumograms of the skull indicated an atrophic lesion on the side clinically opposite that of the epileptogenic focus. The nonvisualization of collections of fluid such as subarachnoidal or intracerebral cysts was the source of most of the errors in diagnosis.

JOHN MARTIN, M.D.

Intracranial Aneurysm of the Internal Carotid Artery in Willis' Polydromal Space. Dandy's Operation. Recovery (Aneurisma Intracranial de la carótida interna, en el polígono de Willis. Operación de Dandy; Curación). EDUARDO C. PALMA. *Bol. Soc. cir. Uruguay* 1947 18 571

A man aged 65 had had an episode of meningeal hemorrhage 1 year prior to admission. His chief complaint was an intensive headache in the right frontotemporal region. The physical examination revealed diplopia, ptosis of the right upper eyelid, pain in the right orbital region and severe headache in the right frontotemporal region radiating toward the neck. The patient's blood pressure was 200/120.

The history of a meningeal hemorrhage combined with unilateral paralysis of the oculomotor nerve and frontotemporal headaches on the right side suggested the diagnosis of an intracranial hemorrhage of the right internal carotid artery. The diagnosis was confirmed by arteriographic findings.

An operation was performed under local anesthesia after a period of 6 weeks during which a digital compression had been employed daily. A frontoparietal temporal osteoplastic flap was formed and an aneurysm of the right internal carotid artery in the region of Willis' circle was exposed. The carotid artery was ligated in such a manner as to leave the anterior communicating branches intact. The mental condition of the patient was not affected during the operation by the ligation.

No serious complications developed during the postoperative course. Penicillin injections and local applications of sulfathiazole promptly eliminated a small area of osteitis in the parietal region. A metallic murmur synchronous with the pulse and probably caused by the clips could be heard during the early stages of convalescence but disappeared later on. The paralysis of the oculomotor nerve remained

unchanged but the headaches disappeared and the great danger of a recurrence of the meningeal hemorrhage caused by rupture of the aneurysm was completely eliminated. JOSEPH K. NARAY, M.D.

The Surgical Treatment of Certain Intracranial Arterial Aneurysms. RICHARD D. SWAIN. *Surg. Clin. America* 1948 38 396.

Although the diagnostic criteria of ruptured intracranial aneurysms are well recognized, the surgical treatment remains a frontier in neurosurgery. The author reports 4 cases of aneurysm of the left middle cerebral artery in patients who have not been considered amenable to surgery. Three of the patients were cured by ligation and coagulation of the aneurysm. One patient had suffered very severe cerebral damage from the aneurysm and although the aneurysm was coagulated there was a partial residuum of the cerebral damage.

The operative procedure was carried out through a left frontotemporo-parietal osteoplastic craniotomy. In each case the aneurysm was located with a searcher inserted into the temporal lobe. In 2 cases an incision was made in the temporal lobe exposing the hemorrhagic area and aneurysm. In 1 case the aneurysm was exposed through the sylvian fissure.

The author strongly advocated the use of a wide-mouthed sucker which not only immobilized the aneurysm but also cleared the field of hemorrhage.

In this remarkable series there were no deaths and in 2 of the patients there were no neurologic sequelae. JACK L. WOOLFE, M.D.

Fundamental Anatomy and Neurology for the Surgical Treatment of Apoplexy (Fondamenti anatomici e neurologici per il trattamento chirurgico dell'apoplessia cerebrale). CORNELIO FAZIO. *Chirurgia* 1947 2 404.

In the author's statistics on 150 cases of apoplexy, it was shown that 54 per cent of the patients died from hemorrhage while 46 per cent died of softening from ischemia or hemorrhage.

Recent publications, especially those of French neurosurgeons, advocate surgical procedures only for the treatment of a certain group of cerebral hemorrhages termed intracranial hematomas. Such lesions are localized in the white substance of the hemispheres, especially in the frontal or temporal regions, and frequently cause an endocranial hypertension.

The author indicates various types of cerebral hemorrhage by reporting personal observations. He draws the conclusion that surgery may be indicated also in cases of hemorrhages in other locations not including those in the nuclei at the base of the brain and erroneously called capsular hemorrhages. Excellent results may be obtained with surgery in intra-cerebellar endoventricular hematomas.

In differentiating cerebral hemorrhages from tumors, ventriculography, encephalography and arteriography are of great help.

ARTHUR F. CIPOLLA, M.D.

Voluminous Angioma at the Base of the Brain (Voluminoso angioma della base encefalica) F. MASCHERPA and A. PALERMI. *Chirurgia*, 947: 335.

Malformations and tumors involving the blood vessels may be divided into the following groups: (1) angioma cavernosum, (2) angioma racemosum, (3) anglioreticuloma, and (4) anglioglioma. The second group includes several varieties of tumors, the arteriovenous aneurysm being the most important from the clinical point of view. Various other terms have been applied to it, namely: arterial angioma, circoed aneurysm, arteriovenous angioma, arteriovenous aneurysm, aneurysmatic angioma, or arteriovenous hamartoma.

The author treated a 10-year-old patient who, at the age of 8 years, developed a left hemiparesis accompanied by headache and vomiting, hyper-tension, papilledema, and lymphocytosis of the spinal fluid appeared a few days later. A similar episode developed 1 mo. later after the first.

Encephalographic studies revealed the presence of a mass in the lumen of the right lateral ventricle. Arteriography disclosed an angiomatic mass, directly communicating with the corresponding internal carotid artery in the lower portion of the right cerebral hemisphere.

Following intensive roentgen therapy all symptoms disappeared and a check-up examination 8 months later showed the patient to be in a good condition.

The author calls attention to the curative effect on angiomas of intensive roentgen treatment.

JOSUË K. NAR. M.D.

End Results following the Capsular Operation for Parkinsonism. JEFFERSON BROWDER. *Surg. Clin. N. America*, 94:3, 339.

The capsular operation for the relief of Parkinsonism consists of the section of the fibers of the anterior limb of the internal capsule up to a few millimeters rostral to the genu of the internal capsule. This operation should be limited to patients under 50 years of age and preferably those having definite unilateral predominance of symptoms. It should be remembered that the operation is definitely palliative and does not alter the usual course of the disease. Although it may be performed on the dominant hemisphere, a transient speech defect may be anticipated during the postoperative period for approximately 3 months. Aside from the complications of surgery there is usually no paralysis. A mild paresis is often present and is usually desired although, in some patients, there may be no discernible paresis.

The author suggests that the operation be performed only on one side. If however there is bilateral involvement, the opposite side might be brought under control by a posterolateral chordotomy as advocated by Putnam.

The article was derived from a symposium on neurosurgery and does not give a complete discussion of the operative procedure or the percentage of

results and complications. Three cases with variable results are presented and discussed.

JACK I. WOOLY, M.D.

SPINAL CORD AND ITS COVERINGS

An Evaluation of Curare in Spasticity Due to Spinal-Cord Injuries. ROBERT A. KIRBY and DONALD S. BICKER. *N. England J. M.*, 94: 121, 65.

The authors attempted to evaluate the effect of curare in 34 patients who were suffering from spastic paraplegia due to complete or incomplete traumatic lesions of the spinal cord. They conducted an independent series of study. In the first, 17 patients received intramuscular injections of 175 mgm. of d tubocurarine chloride in oil and white wax over 48 hours for 10 doses, and in the second, 17 patients were given an equal volume of physiologic saline solution intramuscularly throughout the same treatment period. No differences in the patients' reaction could be found in the two series.

The authors observed no relief of the spasm or other beneficial effects from the treatment of spasticity by the injection of tubocurarine in oil and wax, and toxic effects were frequent. However transient beneficial effects were reported following the injection of aqueous curare.

GROVER PARKER, M.D.

PERIPHERAL NERVES

The Effect of Occlusive Arterial Diseases of the Extremities on the Blood Supply of the Nerve: Experimental and Clinical Studies on the Role of the Vasa Nervorum. JOSEPH THOMAS EMMERS. *Am. Heart J.*, 1943, 35: 369.

Attention is called by the author to the importance of the circulation of the peripheral nerves in relation to their physiological activities. Experiments have been conducted to determine the effects of devascularization of the peripheral nerves.

The various types of experiments undertaken were as follows:

1. Ligation of a segmental nutrient artery of a peripheral nerve dogs being used as experimental animals. A segmental nutrient artery was divided between ligatures without trauma to the nerve. Chicago blue dye was then injected into the aorta, and the animal was sacrificed. No clinically discernible evidence of dysfunction of the sciatic nerve was found following this procedure. When all nutrient arteries coming to the sciatic nerve between the hip and knee joint were destroyed, weakness of the extensor muscles of the foot and of the hamstring muscles was noted.

Histologic study revealed only occasional degenerated axones, especially near the periphery of the nerves.

2. Stripping of the perineurium was carried out in varying degrees. When stripping was carried out over a distance of between 1 and 3 cm. no changes in nerve function were noted. However when the

SURGERY OF THE NERVOUS SYSTEM

epineurium was stripped away from all or most of the segment of the nerve between the hip and knee. Impaired function of the nerve was shown by weakness of the extensor muscles of the foot and of the hamstring group of muscles by drop foot with trophic ulcers on the dorsal surface of the foot and partial or complete loss of sensibility to pin prick pinching or heat.

Histologic study in this experiment revealed degeneration of many axons especially those with large myelinated sheaths. Axons near the periphery of the nerve bundles were affected more than those in the central part of the nerve.

3. Stretching of the nerve was accomplished only by severing of the knee joint and consequently no survival studies could be made. Dye was injected into the aorta while the nerve was being stretched and the animal was then sacrificed. Examination revealed the stretched nerve to be white, showing very little injection from the dye which indicated that the vasa nervorum may be obliterated by stretching the nerve.

4. Constriction of the nerve by tourniquet followed by injection of the dye revealed a considerable degree of ischemia of the nerves at the point of constriction and for several centimeters below although the tourniquet had been so placed as to compress all structures except the femoral artery and vein.

5. Obliteration of the vasa nervorum was obtained in several animals by injection of sterile graphite or Lycopodium spores into the nutrient artery of the left sciatic nerve. Evidence of impaired nerve function was found upon recovery from the anesthesia, and there was further evidence of nerve deficit evidenced by decreased sensibility to painful prickling pinching or heat over the area supplied by the branches of the devascularized sciatic nerve. After a few days to two weeks loss of tone, severe wasting trophic ulcers and dry gangrene developed.

Histologic examination revealed degeneration of the nerve below the site of impaired blood supply similar to that which would be expected with severance of the nerve.

Several reports are included of cases in which vascular occlusion resulted from emboli due to coiled dental disease, such as subacute bacterial endocarditis chronic thrombosis, diabetes and other conditions.

The injection of dye has shown that the blood supply of the nerves is quite abundant, and can be seriously impaired or obliterated by the various procedures described.

HOWARD A. BROWN M.D.

Plasma Silk Suture of Nerves. JAMES E. BATEMAN
Ann Surg 1948 127:456

This article is based on the combined use of plasma and silk in the union of 350 divided human nerves. Two silk sutures are placed one fourth inch from the nerve ends to aid in gross approximation and release of tension. Plasma is used for the finer approximation and as a protective covering at the suture line.

The technique of plasma preparation does not depend upon anticoagulants. Thirty cubic centimeters of blood are withdrawn from the patient into a sterile test tube after the operation is started. This is centrifuged in ice-lined containers for a period of 3 minutes at 2500 r.p.m. The plasma is kept in ice until needed. It is then poured into a mould of the type devised by Tarlov.

The author lists some of the limitations of this method of nerve approximation. Application of the mould in inaccessible regions is awkward some injuries cause great loss of nerve and severe tension results.

The following advantages of the combined silk plasma technique are given. By avoiding sutures proximated ends is avoided. By avoiding sutures at the line of union there is less danger of damaging the nerve bundles and initiating bleeding. The plasma aids in the immobilization at the suture line and favors the growth of nerve fibers across the gap in orderly fashion. The protective covering of the plasma minimizes the encroachment of fibrosis from adjacent structures into the suture line.

DANIEL RUOFF M.D.

SYMPATHETIC NERVES

Indications for Sympathectomy in the Treatment of Hypertension. THOMAS FINLEY Surgery 1948 33:639

The author points out that anyone studying large groups of sympathectomized hypertensive patients must be impressed by certain facts. In particular these are that the operation has not been placed on a rational basis, it seldom produces manometric cure, it is often followed by spectacular improvement of symptoms the results are apt to be temporary and that the treatment is violent. It is pointed out also that hypertension is not a disease but a symptom and hence many factors in the normal organism may play a part in its production. All of these factors have a vasoconstrictor influence and either the effect of one or the summation of many of these may be the stimulus in the production of hypertension. The factors are listed as (1) constitutional (2) arteriosclerosis (3) renal (4) nervous (5) endocrine (6) pregnancy and (7) unknown factors. Since we do not know the exact mechanism by which sympathectomy produces its beneficial effects in the hypertensive patient, it is impossible to carefully evaluate its influence on these various factors.

In a study of 100 hypertensive patients who had undergone bilateral splanchnicectomy and sympathectomy, the author has come to the definite opinion that the peripheral vasodilatation and enlargement of the vascular bed is only temporary. He has invariably found that the blood pressure slowly rises after surgery to somewhat near or below the preoperative level. Since postural hypertension usually disappeared within 1 year in the majority of cases this effect is considered an undesirable complication of surgery rather than an asset. With

the present evidence of the humoral theory of hypertension the possibility that sympathectomy may modify the chemical composition of the blood in some favorable manner must be considered. Modification of the activity of the adrenal cortex must also be considered a possibility in the mechanism of the effect of sympathectomy. Although the possibility of the psychic effect of sympathectomy upon the blood pressure of the patient has been suggested by some this does not seem to be a very likely possibility. There is no reliable test that will give a satisfactory indication of the effect of sympathectomy. The more common procedures such as the cold pressor test, the amylal sedation test, splanchnic block and the induction of high spinal anesthesia have all proved unreliable.

In the authors' experience the amylal test has usually given false optimistic results. In view of this the feeling is that disappointments will be fewer if the operation is reserved for those with disabling symptoms and those with early malignant hypertension, but the manometric results will, of course, be better if the patient also has a labile blood pressure.

JACK I. WOOLR, M.D.

MISCELLANEOUS

Hypertension—Etiology and Surgical Treatment.
GROFFET BOURNE. *Br J J* 1948, 435

In the light of some of the recent works of Trueta and his coworkers at Oxford in 1947 the author expresses some of his views regarding the etiology and surgical treatment of hypertension.

By experimental work on animals, Trueta proved that an extreme degree of cortical renal ischemia can be temporarily produced by vascular spasm. Furthermore, during this state of cortical spasm the blood is by-passed through the juxtamedullary glomeruli back into the vasa recta and so into the renal vein. The cortical ischemia is fairly persistent and is produced by various nervous stimuli, but it also can be brought about by a humoral agency such as a posterior pituitary extract.

The success of sympathectomy for hypertension is likely to vary greatly according to the stage of the disease and the underlying pathological state, which therefore must be considered separately. During the first stage the increasing blood pressure may well be caused solely by spasm of the renal cortex, at first transitory, but later continuously involving varying areas of the renal cortex for most of the 24 hours. During the second stage permanent organic

renal disease will result from arterial degeneration and will constitute a permanent source of renal cortical anoxemia. Thus in each of these two stages the hypertension can be explained on the renal theory. In both states the renin comes presumably from transitory cortical spasm, and during the second stage it also comes from permanent cortical ischemia due to arteriosclerosis.

It is the author's feeling that during the first stage, sympathectomy is indicated and will produce a good result. However, in the second stage the result will be poorer. He also presents several cases in which there has been a definite decrease in the size of the heart and improvement in the respiratory function following sympathectomy.

The effect of sympathectomy upon hypertension appears to vary considerably from case to case. The general experience hitherto seems to be that the operation is most successful in younger patients, particularly those under 40 years of age and those in whom the diastolic blood pressure figure is considerably raised so that there is a comparatively small pulse pressure. The operation is usually not helpful in patients with advanced cardiovascular or renal disease, but here exceptions occur, especially in the younger age groups. The author discusses the use of the sodium amylal test and other work up, including retinoscopy by a skilled ophthalmologist, a complete examination of the urine, urea-clearance test, the urine-concentration test, an electrocardiogram, retioscopy of the heart, and sometimes intravenous pyelography. Coronary heart disease is a contraindication to sympathectomy for hypertension.

Careful investigation and observation of a patient with hypertension should have as their chief aim the determination of the following two points: the previous duration of the disease, and an estimation whether the condition is in a stationary stage or whether there is the slightest indication of recrudescence or exacerbation.

There is at present no clinical test available which will enable us to judge the position exactly, but it is probable that a periodic thorough and careful investigation of the renal arteries by a skilled ophthalmologist is likely to provide the best guide to whether the onset of arterial degeneration is beginning to threaten. A periodic careful investigation of the renal function is also desirable in such cases. Finally it is important that every case be considered on its individual merits—general, cardiological, renal, familial, and psychological.

HOWARD H. LARSEN, M.D.

SURGERY OF THE THORAX

CHEST WALL AND BREAST

Bleeding Nipples (Sul sanguinamento del capezzolo)
ANTONIO VOLTERRANI. *Chirurgia* 1947: 345

Bleeding nipples were observed by the author in 2 cases of fibrocystic disease of the breast in 1 case of endocannalicular papilloma 1 case of Paget's disease and in 2 cases of dendritic endocannalicular cystoepithelioma.

From his observations the author draws the conclusion that bleeding nipples are not characteristic of any lesion but that the bleeding is caused by diapedesis and rupture of the walls of the capillaries which are in direct contact with excretory ducts or cystic cavities communicating with them.

Among 425 patients with breast lesions, excluding acute mastitis bleeding nipples were observed in 6 or 1.4 per cent of the patients.

Bleeding nipples may be caused by

- 1 Functional disturbances (a) menstrual hyperemia (b) vicarious menstruation (c) neurosis.
- 2 General conditions (a) locomotor ataxia, (b) arteriosclerosis, (c) hemophilia (d) purpura.
- 3 Local lesions (a) trauma (b) inflammatory processes of excretory ducts (c) dysplastic degenerative processes such as fibrocystic disease or primary cystic dilatation of excretory ducts (d) benign neoplasms (e) malignant neoplasms.

Bleeding nipples have neither diagnostic nor prognostic value as far as the treatment is concerned, it is determined by the character of the underlying lesion.

JOSEPH K. NARAT, M.D.

Mammary Cancer G. E. RICHARDS. *Brit J Radiol* 1948: 21: 109.

Cancer of the breast ranks fourth in frequency of the malignant diseases and is responsible for 12 per cent of all deaths from cancer.

Two methods available for treatment are surgery and radiation therapy, either alone or in combination. The results of the proponents of the various methods have varied considerably. Consequently the author analysed all the methods used in a series of 1,271 cases covering the 10 year period from 1933 to 1943. Of particular interest was the author's desire to determine whether certain popular ideas were actual facts namely (1) breast cancer is more malignant in the younger age group (2) induction of the artificial menopause exerts a favorable influence on the course of the disease and (3) radiotherapy is or is not, capable of irradiating the disease.

Radical surgical results with regard to 5 year survival have varied from 22 per cent as reported by Hasgenson and Stout to 36 per cent as reported by Geschickter. The author's 5 year survival rate with the Steinfeld clinical classification was 70 per cent for stage 1 from 25 to 30 per cent for stage 2 and 5 per cent for stage 3.

When radiation therapy was added to radical mastectomy the results were improved. For the stage 1 group of 147 patients who received postoperative irradiation the 5 year survival was 81 per cent. For stage 2 it was raised from 30 to 43 per cent, and for stage 3 from 5 to 13 per cent. Additional use of preoperative irradiation improved the 5 year survival rate for stage 2 from 43 to 50 per cent and for stage 3 from 13 to 45 per cent.

Dissatisfaction is expressed over the present method of attempting to evaluate the disease and its treatment. Several factors should be considered carefully before any form of therapy is undertaken. They are (1) clinical stage of the disease (modification of Portmann's classification) (2) influence of the size and duration of the tumor (3) influence of the location of the tumor i.e. the outer or inner hemisphere, with or without node involvement (4) histopathology of the tumor (5) age of the patient, (6) influence of the ovarian function, lactation and pregnancy and (7) type of operation, i.e. local excision, simple mastectomy or radical mastectomy.

In order to correlate these factors which undoubtedly influence the course of the disease the formula of Lee and Stubenlord called the Clinical Index of Malignancy has been used. To each of the enumerated factors a numerical value is given thus clinical index equals lactation factor plus twice the age factor plus 3 times the site factor plus 4 times the growth rate plus 5 times the stage (C.I.M. = $2L + 2A + 3S + 4R + 5E$). If the clinical index adds up to between 10 and 30 the degree of malignancy is low and the prognosis is good. If the total adds to between 31 and 40 the degree of malignancy is intermediate, and if it is above 40 the degree of malignancy is high and the prognosis unfavorable.

As a result of this extensive analysis the author believes that in the stage 2 group with a clinical index between 10 and 30 therapy should consist of radical mastectomy followed by irradiation only in selected cases. Five year survival should be between 75 and 80 per cent. In stages 2 and 3 with a clinical index between 31 and 40 choice of treatment should be preoperative irradiation, radical mastectomy and in some instances postoperative irradiation. Five year survival should range from 65 to 70 per cent. Patients in stages 4 and 5 with a clinical index between 41 and 60 should be treated by irradiation. Some inoperable patients may become operable. However the majority are cared for by radiation therapy. Five year survival should range from 35 to 43 per cent.

The best results in the treatment of carcinoma of the breast can be obtained by the judicious use of surgery and radiation therapy. Age is not a factor in the prognosis. The value of routine sterilization of women in the premenopausal period is still to be proved. Radiation was able to control the primary

disease in 47 per cent of the patients treated. A general plan for the management of breast cancer is suggested which, if followed, would increase the 5 year survivals and reduce the number of postoperative recurrences.

MARCELO D. SACTI, M.D.

TRACHEA, LUNGS, AND PLEURA

Bronchoscopy in Bronchiectasis in Children. E. LAMONTAGNE. *Ann. Otol. Rhinol.* 94, 57-58.

The literature on the incidence of sinus disease in bronchiectasis is reviewed. The relationship remains indefinite. Bronchoscopy in children is discussed. The authors prefer the use of local anesthesia and the catheter technique. They believe general anesthesia to be time-consuming and tedious. It is rare to find a child 4 years of age or over who cannot be intubated without having to be retrained. Atropin, morphine and barbiturates are given before the procedure, all or part of the medication being omitted in some cases depending upon the age or condition of the patient. One side of the nose, the pharynx, and the larynx are anesthetized with pontocaine in a 0.5 per cent solution. A flexible rubber catheter is passed through the nose and larynx into the trachea, and pontocaine is instilled into the trachea through the catheter. The radiopaque oil is then injected under fluoroscopic control. All lobes of both lungs are mapped at one sitting.

JORIS R. LEXMON, M.D.

Examination of Sputum for Tumor Cells. W. H. MATTHEWS. *Cancer* 11 415-17, 945, 58-59.

Matthews calls attention to the value of employing routine examination of the sputum for tumor cells. Twenty-four hour or overnight specimens are utilized. If abundant sputum is expectorated the morning sample may be used. The bulk of this is enclosed in a gauze bag and fixed in Bouin's solution. Thereafter it is treated as a block of tissue embedded in paraffin, sectioned and stained with hematoxylin and eosin. The diagnostic features are those acceptable for carcinoma cells seen elsewhere in the body, such as abnormally large cells with a large or bizarre nucleus occupying a undue proportion of the cell volume, hyperchromasia, and cells having single or multiple nucleoli. Mitotic figures also may be found.

Thirty-three cases observed over a 3 year period are reviewed. A positive diagnosis was made in 23 cases (73.7%) in which bronchiogenic carcinoma was either proved or reasonable certainty was obtained.

STEPHEN A. ZIEGLER, M.D.

On the Anatomy of the Parietal Pleura and Adjoining Thoracic. K. KIVIAKANGAS and PEKKA TUOVINEN. *Ann. med. exp. biol. fenn.*, 947, 5-293.

The authors present their macroscopic and microscopic observations on the construction of the parietal pleura and adjacent tissue. Five newborn and 30 adult specimens were studied in detail. Samples were taken from the costal part of the thoracic wall

from the region of the mediastinal organs and from the diaphragm. The pleura was observed to be loosely attached to the surrounding tissues. Along the diaphragm alone the connection is firm.

The division takes place in the stratum best to the parietal pleura, consisting in the costal part of the thoracic cavity and in the pericardiac area of thin fibered loose connective tissue and, in many cases, in the area of the great vessels, the trachea, and the esophagus of adipose tissue as well. The construction of the pleura itself displays considerable variety. Often it is made up of endothelium, and a thin stratum of looser tissue between can be distinguished. The pleura can often be cleft into two separate parts, between which the blood vessels, which provide for the nutrition of the pleura, are situated. In the area of the intercostal muscles a membrane of varying thickness may be separated. It is fastened to the pericostum where it meets the costae and must be looked upon as the fascia of the intercostal muscles.

The investigations refute the idea that a fascia endothoracica, i.e. a uniform fascia covering the inner wall of the thoracic cavity exists unless the loose stratum of thin-fibered connective tissue between the parietal pleura and the different organs of the thoracic cavity is to be regarded as such. This last named is the proper stratum in which the extrapleural stripping of the lung has to be performed. The uncertainty that has prevailed up until now seems to be due to the fact that in default of microscopic investigations it was not known that the parietal pleura may be made up of two parts which also can be separated from each other with relative ease.

STEPHEN A. ZIEGLER, M.D.

The Interlobar Pleuritis (Les pleuritis interlobaires). MARCEL BERNARD, PIERRE FRAUST, and JEAN DUMAREST. *J. f. med. chir. thorac.*, 947, 369.

Since 1940, the authors have observed 13 cases of interlobar pleuritis. During the same period they have treated surgically 300 patients with abscess of the lungs. They state that the incidence of interlobar pleuritis is from 6 to 7 per cent of all cases of pleuropulmonary suppurations, with the exception of suppurative pleuritis of the large pleural cavity. Only the indisputable cases have been classified as interlobar pleuritis by the authors.

The diagnosis of this disease is based upon knowledge of the topography of the interlobar fissure. The diagnosis is difficult if only an anteroposterior radiographic film of the chest is taken: a collection involving the entire main fissure will cast a shadow occupying almost the entire lung field except the apex and the costodiaphragmatic angle; a collection localized in one part of the main fissure will cast a shadow occupying only one segment of the lung field and of varying location. This suspended shadow is not at all singular except for its lower border which is well defined and curved (Beitz and Kaufmann).

As early as 1926, Lanoe called attention to the importance of the lateral radiographic film of the

SURGERY OF THE THORAX

chest. He described the spool shadow crossing the lung field obliquely at the level of the main fissure. This shadow will occupy either the entire fissure or its upper or lower segments ending in the neighborhood of the junction of the fissures. The small fissure being anatomically incomplete in a large percentage of the cases is rarely the seat of the pyogenic collection. If the small fissure is the seat of the pathology the base of the interlobar collection in the anteroposterior view will be supradiaphragmatic and will be anterior on the lateral film ending posteriorly near the hilus, overlapping the cardiac shadow in front to the thoracic wall and separated from the diaphragm by a layer of normal pulmonary parenchyma. One must remember that if the collection becomes large the typical spool shadow is no longer present but is replaced by the shadow of a triangle at the inferior segment of a fissure. The characteristic location and direction will however always remain.

With the exception of their localization, the general features of the interlobar pleuritis is similar to that of the encapsulated collections of the main cavity. It sometimes constitutes the residue of a diffuse empyema of the whole pleural cavity. It is usually secondary to a cortical pulmonary focus.

Depending upon the extent of the pulmonary infection, the interlobar pleuritis are classified in two categories: (1) the interlobar pleuritis associated with lung abscess and (2) the clinically autonomic interlobar pleuritis. The former type is fairly common but as a rule is difficult to diagnose. At first all of the signs and symptoms indicate the usual lung abscess and the roentgenogram is of great importance in establishing the diagnosis. There can be an area of consolidation with or without destruction of the lung parenchyma. The lateral film reveals that the area of consolidation is in the immediate vicinity of the fissure and this is also confirmed by the bronchogram. Moreover part of the shadow may take the characteristic shape of a spool. Often however the diagnosis is made only at operation for drainage of the collection thought to be exclusively located in the pulmonary parenchyma. The surgeon will then discover an interlobar empyema communicating with the pulmonary focus through a fistulous tract.

The treatment remains the same no matter how inconclusive the roentgenogram may be of a coexistent interlobar collection. The pleurisy is only an epiphenomenon of the pulmonary focus and will heal following single drainage.

The interlobar pleuritis clinically autonomic, constitute the characteristic picture of interlobar empyema. The patient seeks medical advice because of an infectious syndrome which has an acute or progressive onset and is refractory to sulfonamides and antibiotic agents. Attention is usually focused on the respiratory tree because of a pain in the chest with a diagonal topography. Cough is an important and frequent symptom. The physical examination may reveal restricted dullness characteristic in its shape and localization. In fact it has been learned from

experience that the clinical manifestations exhibited by these patients are very atypical and meager. Very seldom will they lead to an accurate diagnosis.

One cannot overemphasize the frequent coexistence of an aseptic serofibrinous collection in the great pleural cavity which represents a reaction. The typical physical signs are then confirmed by the roentgenogram which reveals a diffuse opacity obliterating the costophrenic angle and extending into the axillary region superimposed on the opacity of the interlobar collection. Thoracentesis yields a straw colored fluid. If one fails to observe that the benign and atypical appearance of such pleurisy is not in harmony with the history and signs of infection one will erroneously attribute the whole pathological phenomena to this pleurisy. The diagnosis of interlobar pleurisy is essentially derived at from the roentgenogram as first pointed out by Lanos and American authors (Sante).

The organisms found in the collection yield as a rule a pure culture. *Pneumococcus* and *anaerobes* are and less frequently *streptococcus* and *anaerobes* are the causative organisms. The authors have never seen a tuberculous interlobar pyopneumothorax.

Much more interesting than the etiology and topography are the radioclinical forms of the condition which have been divided into three types calling for different diagnoses: the first is the pseudotumor type, which must be differentiated from the benign and malignant tumors of the lung; the tuberculous gummas solid cysts, and Aschman's collection; the second type is the interlobar pleurisy with bronchial fistula simulating an abscess of the lung; the third type of interlobar empyema is the pseudocyst. The diagnosis is possible only by reading the lateral film of the chest which reveals a shadow somewhat the shape of a football and crossing the lung field obliquely downward and anteriorly.

The authors point out that the interlobar empyema fail to heal spontaneously most of the time even with the use of chemotherapy and eventually become chronic. Theoretically thoracentesis exploratory or therapeutic, is to be vigorously condemned because of the chance of infecting the whole pleural cavity which is usually free. Thoracentesis may be practiced in certain instances when the interlobar collection as seen under fluoroscopy definitely comes in contact with the chest wall and when adhesions of the pleura leaves exist.

The pleurotomy is imperative and suffices in the great majority of the cases. It must be done in two stages, duplicating the technique of pneumotomy for abscess of the lung.

The prognosis of these interlobar empyemas must be considered as very good when adequate surgical drainage is carried out.

GERARD GAGNON, M.D.

Malignant Neoplasms of the Pleura (In tema di neoplastie maligne pleuriche)
GIULIO TOCINI, Pol
clinico 105 med 1947 54 100.

A malignant tumor of the pleura in a 70-year-old female is described by the author. The present ill

ness began about 4 months previous to hospitalization. The patient complained of a rise in temperature in the afternoon, perspiration, cough and profound asthenia. Later pain developed in the chest with a rise in temperature.

Physical examination revealed an emaciated female with a decreased chest expansion on the right. Auscultation of the lower right lung revealed absent breath sounds with a friction rub above. A slightly tender mass could be palpated in the right upper quadrant of the abdomen.

Röntgen-ray examination of the chest showed dense opacity at the base of the right side that extended up to the base of the scapula. A round shadow was seen in the upper hilus.

Thoracentesis revealed only a small amount of fluid having a specific gravity of 1.020, and containing few red cells and numerous lymphocytes.

The patient expired 4 months from the onset of the disease. At autopsy the right pleural cavity was found to contain a liter of hemorrhagic fluid which caused the left lung to press against the vertebral column. Towards the base of the right lung was found a nodular mass of a dark color. All lymph glands were enlarged.

Histological examination revealed the following: The tissue to be dense fibroconnective tissue. Few nuclei were present in this tissue with finely distributed chromatin. These cells were arranged in tubular or canalicular form and were characteristic of endothelial cells. *ARTHUR I. CROSSLAND, M.D.*

HEART AND PERICARDIUM

Aortic Pulmonary Anastomosis for Pulmonary Stenosis. WILLIS J. POTTS. *J. Thorac. Surg.* 9:43, 17-23.

Cyanosis due to certain types of congenital heart disease can often be relieved surgically. It must be demonstrated that the patient has an insufficient flow of blood to the lungs (as manifested by cyanosis), an increased red cell count, an increase of hemoglobin, a decreased oxygen saturation of the arterial blood, and a markedly decreased tolerance for exercise in order that the condition be suitable for surgery. In patients with typical pulmonary stenosis, as part of the syndrome of the tetralogy of Fallot, roentgenograms should reveal a fairly typical boot-shaped heart with a concavity in the region of the pulmonary conus on the left, a "pulmonary window" in the right anterior oblique and left anterior oblique views, and an absence of pulsations in the hilar regions of the lungs. Electrocardiographs must show a right axis deviation. In patients with tricuspid atresia the heart tends to be globular and slightly flattened on the right, in the region of the right ventricle. In such cases the electrocardiographs show a left axis deviation. A cyanotic child with a large heart or a prominent pulmonary conus with increased hilar markings or visible pulsations in the lung fields on fluoroscopy does not fall into the operable group.

Aortopulmonary anastomosis was performed on 26 patients with pulmonary stenosis and on 3 with tricuspid atresia. There were 4 deaths. While the most suitable age for operation is probably between 3 and 7 years, 13 children who were below 3 years of age were operated on. Successful anastomoses were also done on 2 children under the age of one year—one at 4 months and one at 6 months. The results in the patients who survived surgery have been gratifying. The technique of the operation is given in detail. *SAMUEL KANE, M.D.*

Resection of a Coarctation of the Aorta with Subclavian Aortic Anastomosis. H. H. BRADY, J. L. O'NEIL, and ELLIDA H. BROWER. *J. Thorac. Surg.* 9:15, 9.

The signs and symptoms of coarctation of the aorta form a well known syndrome the diagnosis of which is not difficult if the possible existence of the lesion is kept in mind. The prognosis is poor unless the patient be treated surgically. Approximately 75 per cent die before the age of 40. The condition may remain latent throughout life, death occurring suddenly from ruptured blood vessel or from conditions unrelated to the vascular anomaly. Cardiac insufficiency may occur rather suddenly and progress to complete decompensation and death. Chronic cardiac insufficiency may develop and lead to heart failure and death. Subacute bacterial endocarditis and mitral regurgitation may also occur.

A case is reported in which a 3 cm. segment of aortic aorta containing the coarctation was excised between clamps. When an attempt was made to suture the aortic ends together it was thought that the tension on the sutures was excessive and that it would be hazardous to complete the anastomosis. The proximal aortic stump was, therefore, closed, and the left subclavian artery was freed and divided between clamps at a point 4 cm. from the aortic arch. The distal subclavian stump was sutured, and the proximal subclavian stump was rotated caudad and was anastomosed to the distal aortic stump.

Long testicular clamps were used to occlude the vessel ends while the anastomosis was being done. It was difficult to keep the cut ends of the vessels absolutely immobile in accurate end-to-end approximation. A clamp was, therefore, designed which would firmly grasp the aortic wall between parallel bars without crushing and which would permit the vessel ends to be accurately approximated to each other and immobilized.

The clamp devised is carefully described. It has been employed experimentally on 15 occasions, and has proved satisfactory. *SAMUEL KANE, M.D.*

ESOPHAGUS AND MEDIASTINUM

Esophagogastrostomy in the Treatment of Cardiospasm. DAW C. GILL and CHARLES G. GILL, III. *Surgery* 9:43, 3-17.

The modern use of chemotherapeutic agents has allowed operations designed for the relief of cardio-

SURGERY OF THE THORAX

spasm or achalasia of the esophagus to be accomplished with greater frequency and success. It is probable that the obstruction at the cardioesophageal junction is due to organic factors which are intrinsic in the cardia and to its autonomic nerve supply.

The authors operated upon 8 patients whose case histories are briefly summarized. Although a transpleural approach was used in 5 instances and a transabdominal approach in only 3, the latter approach is recommended. This conclusion is based on the fact that the esophagogastric junction is easily reached transabdominally and that in one patient an empyema complicated the postoperative course. In every case chemotherapy was employed in the early postoperative period.

Seven of the 8 patients were treated by an esophagostomy patterned after the Finney gastroduodenostomy. In the one remaining case the so-called Heinecke Mikulicz procedure was accomplished. This consists in the longitudinal incision through all the layers of the esophagus and stomach on either side of the cardioesophageal junction and closure by transverse suture of the incision.

In most of the patients some unfavorable symptoms referable to the upper intestinal tract persisted after operation. All were benefited by surgery and the function of the esophagostomy as shown roentgenologically was excellent in all of the cases. In 5 of the 8 patients there was an appreciable gain in weight. The esophagus returned to normal size in 5 of 7 patients in whom the esophagus was dilated and elongated decreased only slightly in one and did not change in size in the last.

The theory receiving most support at the moment is that surgery should be reserved only for those cases which are refractory to other forms of treatment. However, the authors suggest that many of these patients with cardiospasm should be operated upon earlier before irreversible changes in the esophagus occur.

Bronchiogenic Cysts of the Mediastinum HERBERT C. MAIER, *Ann Surg.*, 1918 127 476.

A considerable number of bronchiogenic cysts occurring in the mediastinum produce symptoms of varying degrees of severity due mostly to pressure

upon the adjacent structures. Those cysts which remain asymptomatic are found either on routine roentgenography of the chest or as incidental findings at autopsy. They are the results of abnormal budding or branching of the tracheobronchial tree. Continuity with the bronchial lumen may be lost in the event that the cells become separated from the parent structure.

The cyst is usually spherical or loculated and is lined by ciliated columnar epithelium. Its wall contains mucous glands, cartilage, elastic tissue and smooth muscle. Secondary inflammation may destroy the epithelium so that its bronchiogenic origin may be difficult to prove.

In the absence of infection the symptoms produced by bronchiogenic cysts depend chiefly on the size and location of the mass. When secondary infection occurs the symptoms are those of an intrathoracic suppuration, particularly those of a mediastinal or pulmonary abscess. According to the degree of bronchial obstruction either obstructive emphysema or atelectasis may occur.

The roentgenogram of the chest may not demonstrate the cyst because it is usually hidden among the mediastinal densities. Occasionally an oblique film will demonstrate the lesion. The fact that bronchiogenic cysts most often are located in the posterior mediastinum serves to differentiate them from the more common dermoid cyst occurring in the anterior mediastinum. Cysts of bronchial origin may move and change their shape with respiration, which suggests their cystic nature and relationship with the tracheobronchial tree.

Since mediastinal tumors in general should be excised the failure to obtain a correct preoperative diagnosis is not necessarily a great disadvantage. The transpleural approach is recommended because of the access provided to both pleura and mediastinum. If complete removal of the cyst wall seems hazardous it is permissible to allow a portion of it to remain *in situ*.

Eight illustrative case summaries accompanied by excellent roentgenographic reproductions are presented to emphasize the clinical and pathological problems associated with the diagnosis and treatment of bronchiogenic cysts of the mediastinum.

OXVILLE F. GRIMES, M.D.

SURGERY OF THE ABDOMEN

ABDOMINAL WALL AND PERITONEUM

Incisional Hernia Repaired with Tantalum Gauze.
Preliminary Report. NIXSON C. JEFFERSON and
U. G. DAILEY. *Am. J. Surg.* 1948, 73: 375.

One case of surgical repair of a large incisional hernia with tantalum mesh is reported by the authors. The patient had a defect in the upper right quadrant measuring 6 by 8 inches. This was repaired in November 1946 and the authors report a satisfactory clinical result when the article was submitted for publication.

The authors report that tantalum was first used in surgery by Fulcher. The use of plates of tantalum in neurosurgery and for hernia repair has been reported but to the authors' knowledge the use of mesh had not been reported when they completed this article.

Mesh can be used without causing tension on the supporting structures since it serves as a patch to cover the entire defect. Fibrous tissue encapsulates the gauze and becomes adherent to the surrounding fascia which produces a new wall of fibrous tissue.

W. FOSTER MORTONCHERRY, M.D.

Cutis Grafts for Repair of Incisional and Recurrent Hernias. HARRIS MAY and R. GAYLE SPANN. *Surg. Clin. N. America* 1943, 28: 37.

Occasionally certain hernial defects require considerable stronger tissue reinforcement. The authors employ cutis grafts and prefer them to fascial strips.

The graft is a full thickness of skin minus the epidermis. It is placed over the defective area and sutured to the peritoneum of the pubic tubercle, one edge to Poupart's ligament and the other to the fascial covering of the conjoint tendon in the case of inguinal hernia. In incisional hernia the graft is sutured in position over the hernial closure under tension. The subcutaneous tissues are sutured down on the graft to enclose all dead space.

The main advantages of this type of repair are the availability of any size or shape of the tissue graft, the strength in all directions of pull, and the availability of the buried graft.

Fig. (May Spenn) A thin epidermis graft is raised and flinged. The cutis beneath is removed.

It is conceded that more experience is needed to make a final evaluation of this method, but it is believed that the cutis graft will take an important place in the repair of recurrent and incisional hernias.

STEPHEN A. ZIEGLER, M.D.

The Treatment of Peritonitis. A Review of 136 Cases. RALPH H. LOX. *West. J. Surg.* 1948, 56: 300.

World War II provided the opportunity for this study of 136 cases of peritonitis due to abdominal gunshot wounds or gastrointestinal perforations from other causes. There were 30 deaths in the series and 16 autopsies were performed. In 8 cases the cause of death was the presence of missed bowel perforation. Two patients died of splenic hemorrhage, 1 from bile peritonitis due to a ruptured liver and 1 from the toxic effects of a necrotic segment of liver tissue which had been left in the abdominal cavity. The remaining 4 showed minimal peritoneal findings and died from distant toxic effects. These findings demonstrate the importance of complete inspection of the abdomen at the time of initial surgery and the importance of greater consideration of distant toxic effects of peritonitis in view of the better control of infection which is now available.

Fig. (May Spenn) The defective area is covered with a cutis graft, which is sutured to the peritoneum of the pubic tubercle, one edge to Poupart's ligament, the other edge to the fascial covering of the conjoint tendon, and the remaining edge is split at the point of emergence of the spermatic cord from the internal ring.

SURGERY OF THE ABDOMEN

The sulfonamides and penicillin modify previously accepted surgical principles but should not supplant good surgery. With modern chemotherapy there is seldom justification for delaying surgical intervention on the source of peritoneal contamination. Supportive therapy should be directed toward maintaining fluid equilibrium preventing peripheral vascular collapse and meeting nutritional requirements. Pulmonary edema and renal shutdown are to be avoided by the judicious use of fluids and blood. The use of the Miller Abbott tube has been a valuable means of controlling distention of the small bowel.

The combined use of surgical principles, adequate supportive measures, chemotherapy, and antibiotic therapy has resulted in a marked lowering of the mortality of peritonitis. The type of combined therapy used in this group of cases is discussed but recognition is given to the necessity of keeping an open mind in regard to the ideal chemotherapist to be employed.

JOHN L. LINDQUIST, M.D.

GASTROINTESTINAL TRACT

Röntgenographic Studies of the Gastrointestinal Tract following Section of the Vagus Nerves for Peptic Ulcer. MAX RIVKO and IRENE A. SCHAUER. *England J. M., 1948 238 496.*

The authors of this article are primarily interested in the roentgenographic study of gastrointestinal tract function following section of the vagus nerves for chronic intractable peptic ulcer. A brief review of the literature includes the work of Dragstedt, Grimson, Moore, and their respective coworkers. Attention is directed toward alterations in gastric motility following vagus nerve resection.

At the Boston City Hospital since December 1945 there were 33 patients who had bilateral vagus nerve resections. Twenty nine of these patients had trans thoracic vagotomies and 4 patients had trans abdominal vagotomies. All were studied repeatedly by roentgenography.

Twenty-one of these patients had had no gastric surgery prior to vagus resection. Three had had previous gastroenterostomies with persistence of ulcer symptoms. Of 5 patients who had had partial gastrectomies, 3 had developed intractable marginal ulcers and 2 refractory jejunal ulcers.

Results of x ray study reveal that in the early post operative stages there was a definite gastric dilatation and atony in most cases. Sluggish and arrhythmic peristalsis or lack of peristalsis was often associated with dilatation and atony. Emptying times were markedly delayed. These changes were distinctly less noticeable in patients who had had previous gastric surgery.

Follow-up studies showed a return toward normal gastric function within 6 months to a year after operation. Complete return to normal was not found however in only one case was the follow up period as long as 24 months. In this patient the stomach was slightly dilated with peristalsis of good quality and a 6 hour gastric residue of 5 per cent.

The operation was successful in promptly healing all of the ulcers. The results were especially striking in the patients with sternal and jejunal ulcers. Tenderness was not present on fluoroscopic palpation and no ulcer crater was demonstrable postoperatively. The small bowel was not remarkable in size or mucosal pattern. The motility was slow apparently because of delay in initial gastric emptying as the emptying time decreased the motility became normal.

EDWARD F. LEWISON, M.D.

Tetanus Infection as a Complication of Emergency Surgery on the Gastrointestinal Tract. *Esclusione del Rectum (L'infezione tetanica quale complicazione di interventi di urgenza sul tubo gastro-enterico escluso il retto)* GIUSEPPE SPADARO. *Glor. Ital. chir.* 1948 4 19.

From June 1940 up to January 1947 5 cases of tetanus following emergency operations on the endo-abdominal portion of the digestive tract were encountered in the Pellegrini Hospital in Naples. In one case the infection developed following palliative intervention for perforated gastric ulcer in another following appendectomy for acute appendicitis in a third following laparotomy for intestinal occlusion resulting from volvulus of a loop of the small intestine on its mesentery. In 2 instances the infection developed subsequent to the Bassini herniotomy for incarcerated inguinal hernia. This number of tetanus cases following emergency operations on the gastrointestinal tract (exclusive of the rectum) comprised 18.5 per cent of all tetanus cases occurring in this hospital during this period (27 cases). In addition to the 5 cases reported the author has been able to find only 42 other such cases reported in the world medical literature.

The most important aspect of these cases of tetanus is of course the question of the source of the infection. Introduction of the tetanus bacillus on the surgeon's instruments is today pretty well ruled out. The catgut suture material has been pretty well proved to be free of tetanus spores however in one of the hernia cases a bit of catgut was discharged from the small local abscess which was opened shortly before the appearance of the symptoms of tetanus (an bacteriologic study). As regards the skin in the area of the incision its participation in the introduction of tetanus spores can of course never be entirely excluded despite the most careful disinfection of the area and despite the utmost care in fixing the sterile sheets or towels in the edges of the incision. The possibility of infection is especially great in the patients who live close to the soil. Two of the patients in this material were farmers and one was a carter. The activation of a latent focus of tetanus in the tissues of the patient himself may be caused by the trauma of the operation or by the original inflammatory or other condition for which the patient was operated upon however the author does not raise this possibility for any of the cases here reported. Lastly there remain the possibility of the content of the intestine as the source of the infection.

tion. Of course the normal intestinal mucosa is admitted to be (in all probability) an insuperable barrier to the tetanus bacillus; however, in the case of perforation of gastric ulcer the patient had eaten shortly before the operation and could have ingested some tetanus spores which might have escaped the gastric succus and thus gained entrance to the peritoneal cavity, and in the case of volvulus the symptoms of obstruction had started 6 days before the onset of the intestinal obstruction, and this would have been just enough time for alterations in the involved intestinal mucosa to have made it a possible portal of entry. However, the number of cases are too few to permit of definitive conclusions.

In the matter of mortality 4 of the patients developed symptoms of tetanus within 3 days after the operation, the process an acute course and despite heroic dosages of antitetanic serum, death resulted in all of these cases. In the fifth case the case of volvulus, the intestine was not opened and tetanus did not appear until 3 days after the operation and the patient, under treatment with serum consisting of 50,000 I U given intraspinally, 20,000 I U given intravenously, and 20,000 I U given intramuscularly daily, recovered from the attack.

The author concludes from his personal experience with the material here reported and from his study of the literature that: the so-called traumatic tetanus the prognosis is much graver than in the other forms of this infection commonly encountered.

JOHN W. BROWN, M.D.

Treatment for Gastric Ulcer. SAMUEL I. M. SWALE and MARK L. WELLS. *J Am M Ass* 94:8 36 748.

Benign gastric ulceration was diagnosed in 800 patients seen at the Lapey Clinic, Boston, during the year period from 1936 to 1945. During the same period approximately 8,000 patients with peptic ulcer were treated; hence the ratio of duodenal to gastric ulcer was found to be 9:1 a finding which compares favorably with the statement of Justermans that duodenal ulcer is ten times more frequent than the gastric variety. In 31 of the 800 cases diagnosed as benign gastric ulcer partial gastric resection was carried out and pathologic study revealed carcinoma in 26—a diagnostic error of 9.8 per cent. The total incidence of proved malignancy for the entire group of patients treated medically and surgically was 26 (3.3%) which is assuming the unlikely possibility that none of the patients treated medically proved later to have cancer. Many of the patients operated upon were submitted to resection because of failure of the lesion to heal, i.e. because carcinoma could not be ruled out. Seventeen of the 26 patients had been under medical treatment for a month or longer a period of observation which the authors consider to be too long. Since a benign ulcer of the greater curvature is an extreme rarity it should not be treated medically. Further confusion in diagnosis is caused by the apparent favorable response of malignant ulcers to a medical ulcer regimen; the

lesions appear to become smaller on roentgenologic study but never quite disappear.

Gastric ulcer is four times more common in men than in women and the majority of cases in the authors' series occurred in the fifth decade or later, the so-called cancer age. Gastric symptoms of benign and malignant ulcers are likely to be similar; weight loss is a prominent feature of both groups, and 80 per cent of patients with distress arising from malignant lesions were relieved by food or alkali. Acid determinations are surprisingly parallel in both groups: free hydrochloric acid was present in patients with malignant lesions and anachyly occurred in those with benign ulcer and vice versa. Malignant ulcerations were found to be greater than 2.5 cm. in 61.5 per cent of the cases, but mere size is not a criterion for differentiation since small ulcers occurring anywhere in the stomach often were found to be malignant. Lesions arising in the prepyloric area, the greater curvature, and the cardia should particularly be suspected of malignancy.

The authors state that it is their considered opinion that the treatment of gastric ulcer is primarily surgical and that a trial on medical management is possibly indicated only in a few cases of acute ulcer. The latter should be observed in the hospital and surgery should be resorted to promptly in the event of nonhealing or of failure of the ulcer defect to disappear during a short period of hospitalization. Surgical results of partial gastrectomy were in general considered to be excellent and there was but one recurrence in an uncomplicated patient in the series of 105 benign ulcers subjected to operation.

WAYNE F. CAMERON, M.D.

Peptic Ulcer. HAROLD LINCOLN THOMPSON. *J Am M Ass* 94:8 36 752.

The author presents a review of the complications of peptic ulcer with particular reference to pyloric obstruction, acute hemorrhage, and acute perforation into the free peritoneal cavity. Indications for surgery in peptic ulcer are largely confined to the complications of the disease and range from relative indications for intervention as in the case of intractability, or possible malignant degeneration to absolute indications as in the case of acute perforation. It is with the latter that the article is primarily concerned.

Obstruction of the pyloric outlet is of two types: (1) an acute transient obstruction due to spasm and edema and usually associated with an active ulcer located at or near the pylorus, and (2) chronic obstruction resulting from organic cicatricial stenosis. In either case the treatment begins with decompression by continuous suction and the correction of systemic factors such as hypoproteinemia, avitaminosis, chloride depletion, anemia, and hyperacidity. Antispasmodics are of value in the spastic type of occlusion. The two types of obstruction may be distinguished by their clinical course and by the response to treatment. In the acute transitory variety medical treatment is warranted for so long

SURGERY OF THE ABDOMEN

as relief is obtained. In the chronic stenosing obstruction surgical intervention is ultimately required and should be applied before the patient is nutritionally depleted. Subtotal gastrectomy by the Polya Hofmeister technique is a satisfactory procedure. Vagotomy with gastroenterostomy has given good results, but it is too early to critically evaluate the operation.

Peptic ulcer is the cause of bleeding in approximately one-half of all cases of hematemesis. Eighteen per cent of deaths resulting from peptic ulcer are due to hemorrhage. Clinically, two types of this complication are recognized. First there is a large group in which the hemorrhage is minor moderately severe, or remittent, and in which there is either a favorable response to medical management or a sufficient interval can be undertaken. Second there is a smaller group in which an acute massive uncontrollable hemorrhage occurs and eventually leads to a fatal termination. Surgical intervention during active bleeding in this group may prove a lifesaving measure.

The highest degree of clinical judgment and operative skill are required in handling cases of severe hemorrhage; there are no positive means during the early stages of bleeding of determining which patients will respond to medical treatment and which ultimately will require surgical intervention. Yet to delay beyond 48 to 72 hours greatly increases the mortality in those requiring operation. In the selection or rejection of patients for surgical treatment the following factors must be considered:

1. *Age of patient.* Probably age alone is the most important prognostic point in ulcer hemorrhage. In patients younger than 45 years the mortality with conservative treatment is less than 5 per cent. In patients older than 45 the mortality is 30 per cent. Hence Finsterer's rule of operation during the first 48 hours should be applied to good risk patients in this group. In surgery after 48 hours the 30 per cent mortality rate again obtains.

2. *Advance knowledge of the presence and location of the ulcer* is of value in locating the source of the bleeding. Those patients who are known to have chronic penetrating ulcers in the region of the pancreaticoduodenal artery are likely candidates for immediate surgery.

3. *Recurrent hemorrhage* indicates an increasing danger of fatality, particularly as the patient approaches the critical age. It must however be remembered that the initial hemorrhage may be fatal.

4. *Severity of hemorrhage* as manifested by vomiting of gross blood, tarry stools, weakness, pallor, dyspnea, tachycardia and fall in the blood pressure requires consideration for urgent surgery. The hematocrit is the best index of blood loss. Evidence of continued bleeding is found if after multiple transfusions the systolic pressure remains below 90 and the pulse above 130. Since some patients respond promptly to conservative treatment the best criterion for surgical intervention is found in the pa-

tient's response to treatment while he is given half hourly checks on the pulse and blood pressure. It should be kept in mind that the decision should be made during the first 48 hours.

5. *Associated disease* (arteriosclerosis, hypertension and coronary sclerosis) within reasonable limits, is an absolute indication for surgical treatment since pronounced secondary anemia superimposed upon these states leads to anoxia, hypoproteinemia and hyperazotemia, which are more likely to lead to death than a skillful operation to control the bleeding. Proper surgery is directed at adequate visualization of the bleeding point and ligation of the vessels in healthy tissue before they enter the ulcer bed. When possible the ulcer may be excised. Subtotal gastrectomy is carried out after bleeding has been stopped.

Acute perforation is the most sudden severe and disabling complication of peptic ulcer and save for the "formes frustes" type, is in most quarters held to be an absolute indication for surgical intervention. In the typical case in which severe pain, boardlike rigidity of the abdomen, and shock are present there is little difficulty in diagnosis. For a further reduction of mortality in this complication certain details of surgical treatment are important.

1. The use of spinal anesthesia is generally preferred in patients who are in good condition. In poor risk patients endotracheal inhalation anesthesia with nitrous oxide or cyclopropane is preferable. Curare assists in securing relaxation. Field block may be employed in very poor risk patients.

2. Transverse or oblique incision is preferred to the longitudinal type as the wounds are more readily closed and early ambulation may be employed.

3. Simple closure of the perforation reinforced by a tag of omentum is the only operative procedure indicated. Gastric resection should be reserved for a later stage when the patient is in better condition.

4. No drainage of the wound is done; rather the abdomen is tightly closed after a thorough aspiration.

5. The use of sulfonamides locally has generally been abandoned in favor of parenteral sulfonamides or antibiotics before and after surgery.

6. Postoperatively continuous gastric suction, adequate parenteral fluids and early ambulation are emphasized.

WATKINS CAMERON, M.D.

Peptic Ulcer following Gastric Resection (L. ulceri peptica post resectione gastrica). GIOVANNI RINDOZZI. *Polichinico*, ser. chir. 1947 54: 201.

The author presents a tabulated review of 14 cases of peptic ulcer following gastric resection showing the type of primary operation, the signs leading to reintervention, the radiologic findings, the type of surgery performed and the pathological findings. These cases were found among a group of approximately 500 cases of gastric resection making up 0.8 per cent of the total.

The author then gives an exhaustive review of the literature including the pathogenesis, pathology

symptomatology complications, diagnosis prognosis and therapy. The following points are discussed.

Surgery was resorted to in all cases of marginal ulcer. The operative procedure followed was strictly along functional lines to assure proper emptying of the gastric stump and duodenum and eliminate factors tending to cause hypersecretion. The breakdown depended upon the type of anastomosis performed during the primary operation. Whenever the pyloric portion was found it was removed, if possible. The ulcer bearing area was always resected. Sometimes the operation was performed by resecting the ulcer bearing area in block, at other times this was done by first breaking down the anastomosis. When a jejunojejunostomy was encountered it was resected and the anastomosis made beyond this portion. The aim is to leave a third of the original stomach, but this is difficult to evaluate at times since the size at the primary operation is not known. The anastomosis was transmesocolic in all except one case (antecolic) the latter was done because of a narrow mesocolon. In 2 cases of colic fistula the viscera were separated and the opening in the colon was closed. This was followed by ample gastric resection. No mention is made of vagotomy. LUCIAN J. FRODOFF, M.D.

Further Observations on the Treatment of Bleeding Peptic Ulcer. CRAMTON W. HOLMAN, *Surgeon*. 945, J 405

During the period from 1925 to 1930 patients admitted to the surgical service of the New York Hospital because of hemorrhage from peptic ulcers were treated with a more or less standard conservative regimen which consisted of complete bed rest, nothing by mouth, adequate sedation and supportive parenteral fluids until the bleeding had ceased. Of a total of 161 patients so treated 5 continued to bleed after prolonged therapy and were operated upon as a last resort. During the period 21 patients died a mortality rate of 13 per cent.

With a reevaluation of the foregoing statistics in 1940 it was determined that two particular groups of patients showed a distinctly poor prognosis under the conservative type of treatment: (1) those who failed to improve within from 24 to 48 hours after they had been placed on a strict medical regimen (48% of these would have died had conservative treatment been continued) and (2) those who suffered the first hemorrhage while under a strict medical regimen for a heretofore uncomplicated ulcer. As had been noted by others, it was found that the age of the patient had a significant bearing on the prognosis. In patients under 30 years of age the mortality was 6 per cent, in contrast to the 20 per cent in those 50 years and older. Hence it was decided to operate immediately on any patient who fell into either of the two groups described, particularly if the patient was over 40 years and if his condition in any way warranted the risk.

During the period from 1940 to 1946 when the newly instituted regime was followed the mortality

rate was reduced to 5 per cent. Among a total of 206 patients treated because of bleeding there were 11 deaths. Nineteen patients were operated upon during active bleeding and 4 deaths ensued. Eighty-four patients were operated upon after recovery from bleeding with a 3.6 per cent mortality and 66 were discharged from the hospital without operation.

The results of a 5 year follow-up of the patients hospitalized for bleeding peptic ulcer are shown on the following table.

Treatment	Number	Result	Number
No operation	6	Asymptomatic	33
		Bleeding	36
		Pain	14
		Death from bleeding	1
Gastroenterostomy	—	Asymptomatic	1
		Bleeding	1
		Pain	—
		Death	—
Pyloroplasty	—	Asymptomatic	—
		Bleeding	—
		Pain	—
		Death	—
Gastric resection	13	Asymptomatic	61
		Bleeding	—
		Pain	1
		Death	—

The success of this treatment the author emphasizes, depends on (1) early recognition of patients who will not respond to conservative treatment and (2) operation on these patients as soon as possible after the onset of bleeding preferably within 48 hours.

Gastric resection is the operation of choice both to insure the immediate control of bleeding and a satisfactory permanent result. Lesser procedures, not including vagotomy (which is not discussed) are not advisable and give a very much higher incidence of recurrent bleeding. WAYNE F. CAMERON, M.D.

Malignant Disease of the Stomach Simulating Gastric Diverticulum. CHARLES D. ARMSTRONG and DWIGHT L. WILBUR. *Med. Cl. Y. America*, 945, J 236.

True gastric diverticula are relatively uncommon. The majority occur in females and most diverticula give symptoms in the fourth and fifth decades. They may be classified into (1) true or congenital diverticula—in which the walls contain all three mucosal and muscular coats and (2) acquired or false diverticula—in which one or more of the gastric coats is thinned or broken as the result of disease or unusual strain. These latter are more frequently found than the former and may be further divided into (a) those

SURGERY OF THE ABDOMEN

caused by pulsion (intraluminal pressure acting on a gastric wall impaired by disease) and (b) those caused by traction through the attachment of a gastric wall to external structures as the result of a pathological process. The etiology of the condition is not known although many theories have been proposed.

Outpouchings of the gastric wall occur less frequently than those elsewhere in the alimentary tract which appear in order of descending frequency, in the colon as Meckel's diverticulum in the duodenum pharynx esophagus stomach and in the jejunum.

The congenital type of diverticula are found principally on the lesser curvature of the stomach toward the posterior wall within a few centimeters of the cardia. The acquired diverticula are more diffuse in their distribution. The diverticula vary in size some being as small as a pea others as large as a plum and are connected to the body of the stomach by a neck of pedicle of varying lengths. In most diverticula the mucous membrane is intact, and acute diverticulitis, gangrene and perforation have not been described. Adenomas myomas sarcomas, carcinomas and precancerous lesions may be found in the wall of a diverticulum.

The majority of gastric diverticula are asymptomatic, but they may in themselves produce symptoms as the result primarily of gastrospasm. The symptoms in order of frequency, are (1) pain most frequent in the epigastrium and aching or burning in character (2) belching and abdominal bloating (3) nausea and vomiting (4) dysphagia and (5) bleeding which may occur from erosion of the mucous membrane.

The chief diagnostic aid is roentgen examination with opaque meal. The diverticula are often best seen in the recumbent left oblique position which places the sac in dependency. It may be easily overplaced in the anteroposterior position. Gastroscopic examination is also a diagnostic aid, the diverticulum appearing as a circular hole lying in normal mucosa without infiltration and separated from it by sharply defined margins. Difficulty however, is encountered in deciding whether the diverticulum visualized in roentgenograms by gastroscopy or at laparotomy is actually the cause of the patient's symptoms.

In the asymptomatic majority of cases of diverticulum of the stomach no treatment is required if coexistent malignant disease can be excluded. In symptomatic cases of a mild nature a medical routine of low residue diet, antispasmodics, antacids and sedation usually is satisfactory. If medical treatment is not successful then surgical excision is the treatment of choice.

The surgical approach to the cardiac end of the stomach may be either through the abdominal or transthoracic approach.

The authors report 2 cases of simulation of diverticulum of the stomach by malignant disease.

ELY ELLIOTT LAZARUS, M.D.

The Importance and Significance of the Lack of Leukocytes in Gastric Cancer and Changes in the White Count after Gastric Resection (Importanza e significato della mancanza di leucociti nel carcinoma gastrico e comportamento della serie bianca dopo resezione gastrica) GIACOMO BOCCUZZI and WALTER PAOLINO *Minerva med.* Tor 1948, 39 245

A series of blood counts taken at frequent intervals in patients with tumors of the various portions of the stomach and also of the esophagus and the duodenum liver extrahepatic biliary ducts, and large intestines demonstrated to the authors the great role which the stomach plays in leukopenia. The importance of the antiperistaltic factor in the genesis of digestive leukocytosis has also been clearly shown.

In a number of patients who underwent gastric resection, considerable changes were found not only in the red but also in the white count which demonstrated the role of the stomach in the regulation of hemopoiesis. This regulatory mechanism is not confined to any small portion of the stomach the entire digestive tract participates in it.

Leukocytosis a normal white count or leukopenia may be found in patients with cancer of the stomach. Thirty-seven and one-half per cent of the patients with a tumor in the region of the cardia or fundus had a white count of over 8,000 another 37.5 per cent had a count below 6,000 and 8,000 and 25 per cent had a count between 6,000 and 8,000 and three tenths per cent of the patients with tumors in the region of the antrum had a white count over 8,000 23.1 per cent had a count below 6,000 and 8,000 and 61.6 per cent had a count between 6,000 and 8,000.

The effect of cancer of the stomach on the red and white blood counts is ascribed by some writers not to a direct action but to a cancerogenic toxic effect, hemorrhagic digestive disturbances or osseous metastases.

Absence of digestive or postprandial leukocytosis is not characteristic of gastric carcinoma because it occurs also in catarrhal gastritis, pernicious anemia, simple gastric achylia, and cachexia caused by tumors in other locations in the stomach.

Absence of leukocytosis was noticed by the authors in 80 per cent of the patients with tumors in the duodenum 42.9 per cent of those with tumors in the biliary tract, 34.6 per cent of those with neoplasms in the large intestines and 30 per cent of those with tumors in the liver.

Of 150 patients with ulcers of the stomach 21.7 per cent had a white count of over 8,000 53.3 per cent a count between 6,000 and 8,000 and 20 per cent a count of less than 6,000. Thirty-one patients were subjected to a gastric resection and after the operation 6.4 per cent had a count of over 8,000 38.7 per cent had a count between 6,000 and 8,000 and 54.9 per cent a count of less than 6,000.

In a great many instances the leukopenia found in patients with cancer of the stomach was accompanied by a relative lymphocytosis.

All the aforementioned data demonstrate the great effect of the stomach on leukopoiesis. Castle's factor evidently plays a great role in the genesis of postprandial leukocytosis. Gastric resection by removing a part of the organ which participates in the regulation of hemopoiesis causes alterations in the white as well as the red blood count.

JOSEPH K. VILK, M.D.

Postoperative Hypoproteinemia after Gastrectomies. BJA 48 FALTRIN (Lett. 41, 30, 24, 91 of Supp. 30)

A short review of the literature on hypoproteinemia is presented. Anesthesia, anoxia, shock, hemorrhage, and electrolyte imbalance are factors in the development of hypoproteinemia. Anoxia will be more pronounced during local anesthesia than general anesthesia, and cyclopropan narcosis. The author's investigation was carried out to determine the degree of postoperative hypoproteinemia after gastrectomy and whether the concentration of serum protein showed a correlation with the occurrence of complications. Eighty-five cases of gastric or duodenal ulcer and 38 cases of cancer of the stomach (besides normal material) and material for control and comparison were used in this study. All patients with ulcer except 2 were treated by resection of the stomach, and about one half of the stomach was removed. Either Polya operation with retrocolic, terminolateral anastomosis or Whipple's operation with antecolic, terminolateral anastomosis and suture of the gastroyjunomy in two layers was used. The anesthesia employed was either spinal anesthesia or ether narcosis. Twenty-five of the patients with cancer were operable and 3 were inoperable. All of the patients were given from 3 to 5 liters of normal saline solution subcutaneous during the operation and after the operation, and drop enemas so that they received from 3,000 to 4,000 c.c. of liquid in the first 24 hours. In the noncomplicated cases the patients were given a teaspoonful of liquid by mouth on the first day after the operation and afterward in steadily increasing quantities with the addition of soda water and broth. On the third day the patient usually got two rusks, and on the fourth day also fish balls. Afterward they gradually received a diet of minced meat and mashed potatoes and vegetables. On the third day after the operation an enema was given. The loss of protein through the urine is not to be reckoned with according to the findings. The routine examination of the feces for blood was therefore discontinued.

Eighteen patients examined showed no postoperative variations in chlorides or alkali reserve outside the normal limits. The average amount of serum protein in 30 healthy men and 30 healthy women was equal for the men and women, namely 7 gm per cent, and the nonprotein nitrogen was found to be practically equal for men and women, averaged 3.35 mgm per cent. The average hematocrit value was 43 per cent for men and 40 per cent for women. The serum protein in 61 patients with uncomplicated

gastric or duodenal ulcer was 0.3 gm per cent lower than in the normal material. Variations for the nonprotein nitrogen and hematocrit were small. In 17 (all men) of the 61 patients with uncomplicated ulcer who had been subjected to gastrectomy the operation and the postoperative course were free from complications. The content of serum protein fell on the third day after operation to 84 per cent of the average preoperative value. By the fifteenth day it rose to 92 per cent of the preoperative value. The course of the nonprotein nitrogen was the opposite of that noted for the serum protein and the hematocrit. The nonprotein nitrogen rose to a maximum on about the third day and fell to the preoperative value on about the tenth day after operation. It appeared that the principal cause of postoperative hypoproteinemia after uncomplicated gastrectomy was hemorrhage. The serum protein and hematocrit values decrease a little after tapping of the blood. Three patients with hematocrit and melena were examined.

An experiment was performed to investigate if the preoperative filtration of plasma would prevent the fall in serum protein after gastrectomy. Four patients were given plasma transfusions of 800 c.c. about 6 hours after the operation. It was found that one can prevent the postoperative fall in serum protein after uncomplicated gastrectomy for ulcer by the administration of 800 c.c. of plasma intravenously after the operation. Experiments show that the transfusion of 900 c.c. of blood after the operation can prevent the postoperative fall in the hematocrit value which always occurs after an uncomplicated gastrectomy. It was also seen that the postoperative fall in serum protein was prevented. Thus, the rise in serum protein and hematocrit values coincides with the restitution of the intestinal functions. The serum protein in grams per cent in patients on a diet cure for gastric or duodenal ulcer was investigated before and after 1, 2, and 3 weeks following the commencement of the cure treatment. Examination revealed a very slight fall in the first and second week of the cure treatment, while in the third week the figures are practically the same as those noted before the treatment began. Therefore, the postoperative hypoproteinemia after uncomplicated gastrectomy for ulcer seems to be due mainly to the loss of blood caused by the operation and in some degree to postoperative paralysis of the intestine. In the case of uncomplicated gastrectomy for ulcer no postoperative hypoproteinemia was noted. Cases in which the development of hypoproteinemia was prevented by the transfusion of plasma or blood did not reveal that this procedure had any influence on the postoperative course. The hypoproteinemia regresses spontaneously as the patient recovers after the operation and the gastrointestinal functions are resumed. The serum proteins reach the preoperative value in 2 weeks after the operation.

Transfusion of whole blood is therefore the most suitable procedure. Transfusion of 450 c.c. of blood is not sufficient in uncomplicated cases to prevent

SURGERY OF THE ABDOMEN

entirely the postoperative fall in serum protein and hematocrit. There were 27 complicated gastrectomies for ulcer. Here again it appeared that the most frequent and most important cause of postoperative hypoproteinemia was hemorrhage.

An increased propensity to edema with distinct clinical symptoms was noted in 3 cases. In 13 cases it was found that the postoperative hypoproteinemia was below the so-called edema threshold.

There were 4 cases of disturbance of the process of wound healing. Hypoproteinemia is an important contributory cause of wound disruption. Control examination of the hematocrit ought to be made before, and every day after the operation until the value has come up toward the normal and the patient is out of danger.

There were 38 patients with cancer of the stomach, 28 men and 10 women. In 25 cases gastrectomy was performed. In 13 the condition was inoperable. The average values for serum protein and hematocrit in patients with cancer of the stomach are lower than the average values found in patients with uncomplicated gastric ulcer. Patients with cancer of the stomach were found to have, in general, a lower concentration of serum protein than patients with gastric ulcer and a concentration which was very much lower than that of healthy individuals. The postoperative fall in hematocrit was relatively less and the rise in nonprotein nitrogen relatively more after the operations for cancer of the stomach.

Laparotomy in itself had little influence on the serum protein as shown in 7 cases of exploratory laparotomy in inoperable cancer of the stomach. In these cases it was probably the laparotomy with the resultant gastrointestinal paralysis as well as the reduced capacity for the new formation of serum protein that was the chief cause of the hypoproteinemia. Here again, it was assumed that hemorrhage was the principal cause of postoperative hypoproteinemia after gastrectomy. Patients operated upon for cancer of the stomach seemed to have less capacity for the regeneration of serum protein than patients operated upon for gastric ulcer. A simultaneous pronounced fall in the serum protein and rise in the hematocrit and nonprotein nitrogen values after the operation is a very bad prognostic sign.

RICHARD J. BIERKEIT, JR., M.D.

The Probable Nature of Intestinal Infarction with out Vascular Lesions (Sulla probabile natura dell' infarto intestinale senza lesioni vascolari) ALDO GERCO. *Gior Ital chir.*, 1947 3 637

The author describes a case of intestinal infarction without vascular lesions. An uncertain diagnosis of intestinal obstruction or intestinal infarction had been made. At operation, a loop of small intestine measuring about 110 cm. was found 40 cm from the ileocecal valve. It was dark red in color with hemorrhagic spots disseminated throughout. The corresponding mesentery was of a similar appearance. At the base of the involved mesenteric wedge was a group of enlarged lymph nodes, one of which was as

large as a big nut and covered with necrotic serosa. A white creamy substance having the macroscopic appearance of tuberculous pus was expressed. The enlarged glands were removed. On returning to the involved intestine it was found to be in the same condition even though about 10 minutes had elapsed. At this time 1 c.c. of adrenalin 0/00 was injected subcutaneously. In about one minute the arterial pulsations reappeared and the color improved. The postoperative course was uneventful.

The histologic study revealed amorphous detritus with some degenerating lymphocytes. No acid fast bacilli were found. Roentgenograms of the chest revealed a bilateral parenchymal infiltration in the subclavicular region with incipient resolution.

The literature is reviewed and various theories as to cause of the condition are discussed, such as arterial spasm with local ischemia, infection, and the theory of Gregoire who believes the hemorrhagic phenomena of the intestine to be due to local anaphylactic shock.

The author suggests, from a purely pathogenetic point of view, that this lesion is similar to other conditions such as retractile mesenteritis, chronic terminal ileitis and incapsulating peritonitis. All of these have as a common basis plasmorrhagic phenomena of different intensity and duration. He would regroup these as a single nosological entity called enteromesenteric diseases with altered capillary permeability. In the author's case it would be considered as an acute manifestation—in other similar conditions as a more chronic manifestation.

LUIGI J. FROST, M.D.

A Critical Consideration of the Methods of Operation for Carcinoma of the Rectum (Sul metodo di operazione del carcinoma del retto. Considerazioni critiche) A. CINIATA. *Gior Ital chir.*, 1948 4 1

The most important advance in the surgical treatment of rectal cancer, following Lisfranc's simple perineal amputation of the rectum was abdominal colostomy. This procedure has warranted its popularity by detoxifying the patient by relieving him of the fecal stasis in cases of stricture. The artificial anus also sets the lower intestinal tract at rest and thus helps to relieve the sufferer of the edema, irritative inflammatory processes and necrotic changes in and about the tumor itself.

The author believes that the colostomy should be extended even to the cases without stricture. The tendency has, of course, been to use ever more radical measures in the hope of obtaining lasting cure of the patient; however this consideration has always been limited by the operative mortality. Kraske extended the perineal procedure to include the removal of parts of the sacrum as far as the third sacral foramen and later this was extended to include the entire width of the sacrum to the level of the third sacral foramen; however in addition to the local disadvantages such as perineal hernia, the lack of access to the upper abdominal cavity prevented the approach to the malignant process and management of its dis-

semination upward along the course of the superior hemorrhoidal artery. The next most common route of dissemination is downward towards the perineum; this is best managed by removal of presacral connective and lymphatic tissues by means of a Kraskie operation or one of its modifications. The English surgeons (Lockart Mummery Gordon Watson) follow J. Miles turned away from the abdominoperineal method and cling to the definitive colostomy. This was done both because of the lower operative mortality and because of the trouble experienced with the newly formed perineal anus. However when the perineal anus is properly formed the patient can be educated to recognize the defecation impulse and the regular bowel function which is very

close to normal. The perineal anus has, therefore, lost much of its terror.

The author on the basis of his personal experience prefers the abdominoperineal method with the definitive abdominal artificial anus for the carcinoma situated high up in the sigmoid. However for tumors in the ampulla of the rectum and in the anal canal, which comprise about 10 per cent of all tumors in this region, he prefers the Kraskie amputation with the perineal anus.

JOHN W. BRANNAN, M.D.

War Wound of the Rectum and Anal Sphincter
WILLIAM S. MCCORM. *Surgery* 1943, 23: 653

Forty-one patients with wounds of the rectum and anal sphincter were treated. All except one of the

Fig. (McCorm.) Plastic repair for anal sphincter defect. A circular incision has been made around the mucocutaneous border of the anus and the mucous membrane of the rectum dissected upward for a distance of about 3 inches. Mucous membrane, including the scarred area, is drawn down and. The scar is excised from the exposed anal sphincter. 3. Sphincter muscle has been repaired. Rectal mucous membrane is cut across above the scarred area. 4. The remaining mucous membrane is sutured to the skin to cover the repaired sphincter.

Fig. 4 (McCune) Fascial sling plastic repair for complete anal incontinence. 1 Short incisions have been made on each side of anus posteriorly to expose the lower edge of the gluteus maximus muscle. A strip of ox fascia is pulled through the posterior subcutaneous tunnel from one incision to the other. 2 The end of the strip is drawn back through the anterior subcutaneous tunnel passed through a portion of the gluteus muscle, and tied to the distal end of the same strip, to form a sling around one side of the anus. 3 Beginning at the opposite incision a second strip of fascia is passed in the opposite direction and tied in a similar way to complete the circle. The skin is closed with silk.

wounds were due to gunshot from the enemy the majority being caused by shell fragments or machine gun fire. All of the patients were between 20 and 36 years of age. In most instances no definitive treatment for sphincter incontinence or external rectal fistula had been given prior to transfer of the patient to the Walter Reed General Hospital although in many instances skin grafts, secondary wound closures and rectourethral fistula repairs had been performed. One patient had had two previous attempted closures of a large external rectal fistula. The average lapse of time between the time the patient was received and the first definitive treatment in this hospital was 10 months. This length of time is explained by the fact that most cases were complicated by other conditions which received treatment priority. These included 11 rectovesical or urethral fistulas and numerous instances of sciatic nerve injury, perforations of the colon and small bowel, and compound fractures of the pelvic bones. All patients had had débridement of the wounds and most of them a temporary sigmoid colostomy at the time of injury. Most of them had had local application of sulfanilamide crystals and shock treatment in the form of plasma and blood transfusions.

The classification and treatment of these 41 rectal war wounds and the evaluation of the results of the

various operative procedures employed have convinced the authors of several facts (1) sphincter muscle exercises are of great value in improving anal sphincter power, (2) the best operative results are usually obtained in the cases in which torn muscle ends can be approximated, even though not perfectly (3) the Stone fascial plastic operation has a definite place in the treatment of such patients if the sphincter ends cannot be found (this operation has given enough control to restore many men to fairly normal lives) and (4) when no repair of sphincter power can be devised an abdominoperineal resection is probably the procedure of choice. It must be remembered, however that this precludes any later repair based upon future developments in rectal surgery.

LIVER, GALL BLADDER, PANCREAS, AND SPLEEN

Preoperative and Postoperative Treatment in Hepatobiliary Disease. B. O. C. PRIEBRAM. *Surg Clin N America* 1948 28 403.

For the preoperative treatment of hepatobiliary disease the author recommends the intravenous injection of a mixture of atropine sulfate, morphine, and ephedrine the judicious use of local measures

such as the application of heat or cold, the rehabilitation of fluid balance, liver glycogen, proteins and electrolytes, the combating of acute liver edema by the use of 20 c.c. of a 50 per cent dextrose solution, prophylaxis against cholemic hemorrhage by the use of vitamin K, calcium and vitamin C, and surgical measures in cases of obstructive jaundice. Electrocoagulation is recommended and the procedure is described in detail. Postoperative therapy is directed toward combating shock, the respiratory state, reduced blood pressure, peripheral circulatory failure, peritonitis, hepatic insufficiency, coma, hepaticum and venous thrombosis.

The advantages of mucoclasia, the correct method of employing electrocoagulation and its place in gall bladder surgery form a integral part of the present paper.

STEPHEN A. ZILMAN, M.D.

The Cholelithic Syndrome and Lymph Gland Calcification of the Hilus of the Liver (Syndrome cholelithica, calcificationes lymphoglandulæ deli hepatici) P. 181 (1) *M. med. T.* 1949, 39, 20.

The results of x-ray studies of gall bladder disease are stressed by the author. Certain syndromes can be easily misinterpreted if the diagnosis is based only on clinical and laboratory findings.

The value of roentgenologic studies is illustrated by the report concerning a female patient aged 35 admitted with complaints of attacks of pain in the epigastric region. There was tenderness in the right upper quadrant on palpation. X-ray studies demonstrated a group of calcified nodules at the bright of the transverse apophysis of the second lumbar vertebra. Cholecystography showed that the shadows were located above and posteriorly to the gall bladder. The size, tone and function of the gall bladder the latter tested according to Brønner's method were normal.

Calcium deposits in the lymph glands in the region of the hilus of the liver may be caused by tuberculous or less frequently by typhoid fever. The glands may be found in four locations: (1) along the hepatic artery, (2) along the cystic duct, (3) at the confluence of the cystic and hepatic duct, to the right of the common duct at the free margin of Winslow's foramen, and (4) in the duodenopancreatic groove to the right of the common duct. Calcifications in all these glands can be detected in roentgenograms taken in two directions.

Calcium deposits in a syphilitic gumma or in multiple liver abscesses may also simulate gall stones.

JOSEPH K. KATZ, M.D.

Allergic Cholecystopathy and Secondary Cholecystitis following Dysentery (Allergische Cholekytopathie und sekundäre Intercholekytitis nach Dysenterie) WALTER STROCKMANN, *Deut. med. Wochschr.* 1948, 73, 223.

The author calls attention to the fact that there has been very little in the literature to suggest any connection between bacillary dysentery and gall

bladder disease in contrast to the typhoid-paratyphoid infections. In a series of 426 cases of cholecystitis he has found a history which was positive in such a dysentery in 125 patients, or 29.3 per cent. He admits that the war conditions during the period of these observations may well have altered the number of dysenteries, as these were quite frequent during this time.

In the early part of the series the main complaint of the patients was not suggestive of gall bladder disease but consisted of epigastric pain and some tenderness in the upper right quadrant of the abdomen. Some 2 to 4 months after the dysentery had disappeared more evident symptoms attributable to disease of the gall bladder in the form of localization, ulceration and in some instances fever directed the examination to the biliary tract.

The author considers the possible etiologic connection. He believes it to be an indirect one rather than direct bacterial invasion of the gall bladder. His attention is to the allergic manifestations which have been observed in bacillary dysentery and the secretory activity of the mucous membrane of the gall bladder which shows the effect of an allergic reaction. He believes that a gall bladder which has had a previous allergic response is then more liable to infection by opportunistic bacteria which will in turn affect a normal and normally functioning organ. Once such an infection has occurred, the process is the same as in the ordinary case of gall bladder disease of bacterial nature.

WILLIAM C. BERT, M.D.

A Contribution to the Anatomohistologic Study of Benign Tumors of the Gall Bladder (Contribuição anatomohistológica do estudo dos tumores benignos da bexiga biliar) ANTONIO BLANCH, *Cad. Med. Cir.* 1949, 4, 33.

Benign tumors in the fundus of the gall bladder of children and adolescence are reported. These findings were encountered in 3,000 autopsies which were done at the Pathologic Institute, Hospital P. Monteiro, in connection with the University of Naples.

The benign tumors reported in the literature for this location are fibromyomas, fibroadenomas, adenoma, papillary fibroepitheliomas or benign papilloma, fibroma, myxoma and lipomas. The last mentioned have never been reported in the human being and are known from veterinary reports on a animal pathology.

The author's material includes only adenocarcinoma (2 cases) and adenofibrocarcinomas (3 cases). The latter 3 were so designated because of the presence of evidence of young connective tissue proliferation. The remaining 3 cases were examples of simple benign papilloma. The papillomas are discussed separately because of the author's belief that their pathogenesis is different. None of these tumors occurred in children. In no case was there evidence

of inflammatory changes in the remainder of the gall bladder and in no case were gall stones present.

SURGERY OF THE ABDOMEN

The papillary growths are regarded as benign tumors perhaps on the basis of some constitutional factor (such as that causing warts on the skin) which are stimulated to proliferative growth by some chronic irritative process such as gall stones which was not evident at death or which had disappeared. The adenomyomas however, are regarded as true hamartomas in the sense of Albrecht, arising from fetal inclusions as postulated for tumors of this nature by Aschoff and Bacmeister.

MISCELLANEOUS

Endoabdominal Microtorsions (Sulle microtorsioni endoaddominali) BRUNO SPATOLISANO *Ann. ital. chir.*, 1947 24: 574.

Mondor has been associated with the term micro-torsions the torsions of endoabdominal tissues which in spite of small volume and little functional value are usually accompanied by an imposing symptomatic picture. The tissues usually involved are the appendiceal epiplocae less often the fatty fringe of the mesentery of the appendix, and exceptionally the bydatid of Morgagni of the ovary.

A case report is presented of a 44 year old woman who was operated upon for recurrent appendicitis during a quiescent period. At operation the appendix showed signs of chronic inflammation extending

into the mesentery. At the junction of the distal and middle thirds, a small spherical tumefaction was encountered which presented a dark violaceous color with infarction and beginning necrosis and a movable peduncle about 1 1/4 cm. in length twisted twice from left to right. An appendectomy was performed. The postoperative course in this case was uneventful.

This was considered to be a torsion of a fatty fringe of the mesentery of the appendix. A review of the literature is presented. The etiology is doubtful. Some maintain that infection modifies the constancy of the epiploca in an uneven manner which predisposes to torsion others maintain that infection follows the torsion.

There have been 68 cases reported and of these, 6 involved the mesentery of the appendix. The symptoms vary to such an extent that no definite clinical picture can be given. They may simulate acute subacute or chronic symptoms. The diagnosis before operation has always been in error except for the case reported by Fliske in which Dr. Babcock is said to have made a correct diagnosis. This diagnosis was aided by the fact that the patient had had her appendix removed and there was a palpable mass. The surgeon should keep this lesson in mind when on opening an abdomen he does not find the suspected changes in the appendix or salpinx.

LUCIAN J. FROMMERT M.D.

GYNECOLOGY

UTERUS

Carcinoma of the Cervix in an Urban Population.
A. W. DIMECH and T. R. BROWNE. *Am. J. Obst.*
1948, 55: 669.

The present report concerns a cross section of experience in the treatment of cervical carcinoma in Dallas, Texas, from Jan. 1 1936 to Jan. 1 1946. The age distribution, the amount of time lost by the patient and doctor between the onset of symptoms and the diagnosis of cancer and the frequency of inadequate or inappropriate methods of treatment and their relation to sequelae, are stressed.

The survey shows that women in the vicinity of Dallas who were treated for carcinoma of the cervix, did not seek consultation any earlier than did those living in other parts of the United States. Apparently the educational programs of the American Cancer Society are not sufficiently inclusive, or far reaching. The results presented show that in spite of cancer campaigns waged by State and national organizations and the emphasis that is placed on the subject in the medical schools, there is still room for professional improvement.

Total hysterectomy followed by irradiation as contrasted to irradiation alone did not improve the chance of a 5 and 3 year survival. Actually certain types of sequelae were more common in patients who had undergone total hysterectomy than in those who had not been operated upon. In cases in which hysterectomy is indicated a total excision, properly done, offers no greater risk to the patient than the subtotal operation, and does remove the possibility of later development of malignancy in the stump.

The results reported compare favorably with those collected by others from different parts of the world yet, when it is considered that one fifth of the women received questionable or inadequate treatment it becomes apparent that the physician was responsible for the fact that the results were no better. A wider use of the diagnostic curettage and biopsy and proper visualization of the cervix would have originally given more positive diagnoses of cancer. Also the general use of orthodox therapeutic methods undoubtedly would have improved the survival rates and reduced the number of sequelae.

JOHN R. WOLFF M.D.

Hysterectomy LOUIS E. PRANTZ *Am. J. Obst.*
1948, 55: 646.

The literature of the last decade shows that an increasing number of gynecologists have adopted the total hysterectomy or panhysterectomy as a routine operation, and have reserved the supravaginal amputation of the uterus for special cases. This is a total reversal of the opinions held by gynecologists a quarter of a century ago.

Two hundred and sixty-six hysterectomies performed by the author in 1945 and 1946 are reported. In this group there were 213 abdominal hysterectomies, of which 88.7 per cent were total. Of 53 vaginal hysterectomies included in the series, 86.7 per cent were total.

Under present-day conditions the mortality following panhysterectomy in experienced hands, should not be greater than that of the less formidable procedure. The convalescence has been simplified by proper preoperative care so that the patient reaches the operating table in improved or satisfactory condition, and the postoperative care has been greatly improved.

The technique of operation has not changed remarkably during the past 15 years. One noteworthy point however has been the tendency toward closing the vagina and the abdomen without drainage. Experience has shown that the sulfonamides exert their most satisfactory effect when given orally or parenterally rather than when left in the pelvis before the abdomen was closed.

In this group of 266 patients, 3 died. A gross mortality of 1.1 per cent. Case histories giving the details of these deaths are given.

JOHN R. WOLFF M.D.

ADNEXAL AND PERIUTERINE CONDITIONS

Accidental Intravascular Injections of Lipiodol during Hysteroalpingiography (Injections vasculaires accidentelles d'lipiodol survenant au cours de l'hysteroalpingiographie) R. KELLER, *Gyn. Obst.*
Pa. 1948 47: 7

The author reports a case of massive lipiodol injection into the uterine and periuterine venous plexuses which caused symptoms of pulmonary embolism, the latter being confirmed by roentgenography.

An accidental intravascular injection may occur when (1) too high a pressure is used during the performance of the hysteroalpingiography (2) too large a quantity of lipiodol is used (3) vascular injury is produced by instrumentation (4) abnormal vascular fragility or permeability is present (5) there is patency of the vessels of the uterine mucosa (menstruation, metrorrhagia, chronic infection) or (6) the cavity to be injected is of small size (uterine hypoplasia, obturation of the tubes, salpingectomy).

The intravenous injection of lipiodol can produce two types of roentgenographic pictures (1) a diffuse central shadow corresponding to the injection of the capillaries of the uterus, and (2) shadows of venous trunks more or less filled with lipiodol located on the edges of the uterine wall. These correspond to the uterine utero-ovarian, and hypogastric veins. There is a characteristic shadow produced when the uterine veins are injected with lipiodol. The opaque sub-

GYNECOLOGY

stance does not completely fill the lumen of the veins but produces lacunar shadows with enlargement in some areas arranged in a downward loop.

Once injected into the circulation the lipiodol is dispersed so that it can hardly be seen beyond the genital area. These droplets accumulate at terminal points. Therefore roentgenography can reveal their presence in the lung fields.

In the author's case the diagnosis of pulmonary lipiodol embolism secondary to injection into the uterine veins was established by means of roentgen rays and by analysis of the patient's bloody expectoration which revealed drops of lipiodol.

A massive injection of lipiodol may be lethal. As a rule it produces no or only minor clinical symptoms.

The author concludes his article by reviewing the measures to be carried out in order to avoid such an accident during hysterosalpingography. A manometer should be used and the pressure should not exceed 39 cm of mercury. Vascular injection has been observed, however with pressure much lower than this. Continuous x ray control is imperative during the injection. One should be guided by the patient's reaction. The injection must be stopped if the patient complains of pain. The injection must be slow and continuous. One must absolutely avoid traumatizing the tissues. The use of a malleable cannula is to be recommended. A special period of time must be determined for the hysterosalpingography. The author recommends the twenty first day of the menstrual cycle as the optimal time.

The injection should not be done if the patient has vaginal bleeding.

The injection should be discontinued when an abnormal shadow appears during fluoroscopy.

One must be cautious when dealing with an infantile type of uterus or when one or both tubes have been removed.

GERARD GAGNON M D

Primary Double Tumor of the Ovary (Primární duobílná vaječníkových nádorů) JAROSLAV SYRÝK.
Lék listy 1948 3 149.

A 22 year old unmarried seamstress was suffering from a rather persistent, subfebrile ailment of undeterminable nature. In the course of a consultation with the medical man in charge of the case the author discovered a tumor mass which filled the entire pelvis and extended a bit up into the main abdominal cavity. At laparotomy the mass proved to be 2 tumors, one above the other and both attached in the region of the left ovary. The upper mass was attached by the ligamentum ovarii proprium and attached by the same manner as the normal mesovarium in the same manner as the normal ovary. The normal tube and mesosalpinx were stretched across its anterior surface. It was nowhere adherent and easily delivered from the pelvis. Under this tumor mass was a second tumor attached to the upper tumor by a thin band of connective tissue. The pedicle of attachment of this lower mass was the ligamentum suspensorium ovarii

which contained a dilated branch of the ovarian artery. This lower tumor mass was adherent rather widely to the posterior surface of the broad ligament, to the sigmoid and to the omentum. The two masses together weighed more than 2 kgm. The lower mass is believed to have developed first pushing the upper growth upward toward the general abdominal cavity.

The upper mass corresponding to the real ovary exhibited macroscopic and microscopic findings typical of a seminoma (R. Meyer) the lower corresponding to the supernumerary ovary was typical of a cavernous hemangioma. The rarity of the condition consisted in the peculiar association of the two. In the pedicle of the lower tumor was a thick, dense mass of tissue which histologically proved to consist of lengthy oval spaces enclosed in a dense connective stroma which were filled with a wavy spirillar fibrillary tissue with fusiform nuclei. This tissue was shown by the van Gieson stain to be composed of muscle fibers. On downward penetration into the tumor mass itself by means of serial sections the same muscle fibers—in a bad state of preservation it is true—were perfectly recognizable as they were scattered here and there in the connective tissue septa.

The question naturally arose as to the origin of these muscle fibers. In this regard two theories have been advanced. One hypothesis (Doran, Krömer) maintains that they arise from muscle fibers from the uterine musculature which penetrate into the hilus of the ovary by way of the ligamentum ovarii proprium. It is by this route that the ovary gets its blood supply through the ovarian branch of the uterine artery. The other theory (Henrold, Herzog) claims that they arise from the muscular coat of the blood vessels. The latter concept has been rather convincingly demonstrated by means of fibromyotomies, at least in the case of the ovarian serosal tumors, by Basso. He demonstrated that the blood vessels of these tumors lack an adventitial layer in places and that the muscle fibers of the media tend to invade the surrounding tumor tissues. The author believes that in the present case he has proved the validity of the latter theory. In his patient the cavernous hemangioma corresponding to the second centuriate ovary, had no connection with the hilum of the main ovarian structure and was supplied by a branch of the internal spermatic artery.

JOHN W. BRENNAN M D

Sexually Functioning Ovarian Tumors (Tumori ovarici a funzionalità sessuale) ADRIANO BOMPIANI.
Riv. ital. ginec., 1947 30: 364.

A review of the world literature, comprising the principal articles appearing during the 10 year period from 1936 to 1946 relative to the virilizing and feminizing tumors of the ovary is reported. The new growths considered are the granulosa celled or theca celled tumors the so-called "yellow celled" or luteinizing tumor including the so-called anaprenocortical and Grawitz tumors of the ovary and

finally the arrhenoblastoma. The possibility of their origin from teratomas is discussed but dismissed as still not sufficiently established by the clinical animal experimental histological and hormonal studies so far reported. In fact the author concludes that there is sufficient grounds to justify the assumption that all these neoplasms may arise from various components of the theca of the ovary itself.

The possibility of recurrence and even of metastasis associated with all of these growths is admitted nevertheless, the author favors the local removal of the neoplasm when it is still localized and enclosed in its capsule, especially in young women in the child bearing period. When the new growths show tendencies toward diffuse growth or exhibit adhesions, especially in older women following the menopause be advised total removal of the pelvic organs.

JOHN W. BERRY, M.D.

Malignant Transformation of Cystic Teratomas of the Ovary (Transformação maligna do teratoma cístico do ovário) RENE MENDES OLIVEIRA and LILIA MULLER. *J. clin. gin. fac. med. univ. S. P.* vol. 947 p. 36.

Cystic teratomas are essentially benign, but it is often difficult to establish a clear line of demarcation between benign and malignant processes. There seems to be no man's land between the benign and malignant characteristics of a tumor. The difficulty of ascertaining the true nature of the tumor is increased in the ovary, which in addition to the types of histologic growth observed in all organs, presents also individual peculiarities with marked potentialities related to functional and morphologic diversity. These forms of growth may in some way deviate toward the pathologic side.

Cystic teratoma of the ovary seem to be more frequent than they were thought to be and they do not prevent pregnancy. Their malignant transformation is rather rare although the number of such reports has been increasing recently. The transformation is generally of carcinomatous type: endotheliomas and peritheliomas are rarer than epitheliomas and sarcomas are exceptional. The prognosis is very unfavorable. It is true that the transformation is generally diagnosed late when surgery is confronted by difficult situations. In many cases the formation of metastases is early. The mortality rate reaches 80 per cent, even when cases with early operation are included. Treatment must consequently be radical, and little should be expected from complementary radiotherapy. Radical treatment should also receive due consideration in cystic teratomas of the ovary in which most authors recommend conservative surgery.

At the Gynecologic Clinic of the University of São Paulo 24 women with cystic teratoma of the ovary were operated upon from 1910 to November 1945 and 4 cases of malignant transformation were encountered, an incidence of 8.33 per cent. The second and more recent case is reported.

A woman of 44 had persistent pain with a burning sensation in the left iliac fossa for the past 6 months. The pain became gradually worse and was irradiated to the flank, lumbar region and left lower extremity. During the fourth month she discovered the presence of a round tumor in the abdomen, which increased in size. Deep palpation revealed a tumor that entered the pelvis and was the size of a coconut, somewhat mobile, painless and with an irregular surface presenting small sessile nodules. On vaginal examination the tumor appeared to be the uterine body in myomatous degeneration. The diagnosis was uterine myoma. Operation disclosed a right ovarian tumor which was displaced to the left in front of the uterus; the latter was slightly increased in size and the left adnexa were normal. The tumor was easily removed and the patient was discharged in good condition. However histologic examination of the tumor showed that it was a dermoid cyst with carcinomatous transformation (adenocarcinoma).

Ten months later the patient was readmitted. Her general condition was poor and examination revealed a tumor the size of an adult head, extending above the umbilicus and filling the pelvis completely. Because of her condition she was given morphine therapy but she died a few days later.

The interest of this case lies in the fact that there was an adenocarcinoma, which is a rare form of the carcinoma observed here generally being of the squamous-cell pattern. The dermoid formations of the cystic teratoma were largely destroyed by the malignant neoplasm so that the pathologist could not well establish the origin of this glandular carcinoma, whether it was primary or secondary. The rapidly fatal evolution of this case demonstrates the severe malignancy of these neoplasms.

RICHARD KREML, M.D.

EXTERNAL GENITALIA

Absence of Vagina VIRGIL S. COCKRELL, J. D. M. *ibid.* 947, 36, 85.

The incidence of congenital absence of the vagina is not known but the increasing number of cases of the condition that are being reported causes one to believe that the incidence is much higher than was originally considered. The author discussed the embryologic aspects and the historical development of the treatment of this anomaly and reported a group of 76 cases of congenital absence of the vagina encountered at the Mayo Clinic, described a surgical procedure which he thought adequate and disclosed the results. The patients were seen and treated during the decade ending December 31, 1946. The age of these patients ranged from 14 to 49 years. Sixty-six of the patients were single and 10 were married.

A sufficient number of operations for congenital absence of the vagina utilizing the McIndoe principle with or without a Thiersch graft have been performed in this country and abroad to permit recommendation of this procedure as probably being the best and simplest one for correction of this anomaly.

GYNECOLOGY

There are other methods which will give satisfactory results. This particular method produces a vagina which will be normal in depth, diameter and mobility. The risk of the operation is practically nonexistent. In this series there was no death. The morbidity rate will vary according to the amount of pelvic cellulitis which occurs. The operation is very simple technically, and consists only in the careful opening of the vaginal space and the use of a skin-covered mold or a mold without the skin as the case may be. The principle of mechanical prevention of contraction of the new vaginal tract by means of the mold is the basis for success in every one of these operations. The majority of procedures in which portions of intestine or pedicled flaps are utilized are the final stage operations. The author doubts that the final effect which is obtained by the McIndoe operation can be attained by any other procedure.

Most histologic evidence indicates that the normal vagina is formed from the muellerian ducts and the urogenital sinus. If there is no evidence of muellerian ducts or epithelial buds from them the new vaginal tract had best be constructed by means of a skin graft particularly if there has been much difficulty in dissection. In other cases a graft need not be used. In each of the 76 cases reported reconstruction of the vagina was based on the McIndoe principle. In 70 cases the procedure included use of a Thiersch skin graft. In 6 cases operation was performed without it. The decision as to whether the new vaginal tract should be constructed by the use of a graft must be made at the time of operation.

Primary Carcinoma of Bartholin's Gland ROBERT J. CROSSMAN *Am J Surg* 1948 75 597

Primary carcinoma of Bartholin's gland is reviewed and a case of this condition is reported in a 64 year old woman who had a past history of adenocarcinoma of the endometrium which had been treated with radium roentgen therapy and surgery. Three years following this treatment the patient returned to the author with the complaint of vulvar itching of one month's duration. Examination revealed a solid growth of the right vulvovaginal gland, one half inch in diameter with a small ulcerated area on the surface. The preoperative diagnosis was carcinoma of Bartholin's gland and a complete vulvectomy was done. Three years later there was no recurrence.

Carcinoma of Bartholin's gland was first reported by Kolb in 1864. The author reviews the literature and brings it up to date by adding 4 cases to Aquinaga's table including his own case. The total number of reported cases is now 88.

Statistics reveal that carcinoma of the vulva comprises from 3 to 5 per cent of all carcinomas of the female genital tract and that carcinoma of Bartholin's gland constitutes 2 to 3 per cent of all vulvar carcinomas. Among the author's 18 175 private obstetric and gynecologic patients there were 31 cases of vulvar carcinoma and 1 case of carcinoma of Bartholin's gland.

Four diagnostic criteria for carcinoma of Bartholin's gland have been laid down by Honan: (a) typical vulvar site, (b) position deep in the labia, (c) connection with the gland duct and (d) the presence of intact glandular tissue.

Carcinoma of Bartholin's gland occurs most commonly between the ages of 40 and 60. The youngest patient whose case has been reported was 19 years of age and the oldest 91 years. 22 per cent of the reported cases occurred in women under the age of 30 and 25 per cent occurred in women who were over 60 years of age. Therefore carcinoma must be considered in any patient with enlargement of Bartholin's gland.

The most frequent signs and symptoms are a cystic, painful tumor mass, an abscess or a draining sinus and swelling with soreness or itching the size of the mass varies from that of a pea to that of an orange. Rabson and Meekers reported an average patient delay of 15 months before a physician was consulted. Treatment varies from simple excision to vulvectomy with or without gland resection and radiation therapy (either roentgen or radium therapy) or combinations of these treatments.

Of 47 patients with careful follow up studies 5 survived for a period of 3 years. The author has drawn no conclusion as to prognosis because of the small number of patients involved. J. ROBERT WILLSON M.D.

MISCELLANEOUS

Vaginal and Rectal Pruritus—Etiology and Treatment EDWARD L. CORNWELL *Am J Obst., Gynec.* 55 691

It is the author's considered opinion that vaginal and rectal itching is one of the most neglected fields in medicine. Too many physicians pass over the complaint with ease and give some palliative prescription or order the patient to take roentgen treatments or a douche. This attitude is deplorable. There is always a definite reason for the itching or burning but it takes study on the part of the physician to discover the etiology. There is no definite rule to follow in all cases. There is no patient more grateful than the woman who is permanently relieved of this distressing symptom. The present article is based solely on knowledge obtained in the author's private practice.

Trichomonas vaginalis has been by far the most frequent type of pruritus seen. The author suggests that the physician should become familiar with one line of attack and follow it as a routine changing management only as failure to cure appears in the individual patient. His procedure is as follows: The patient is instructed to insert one Devegan tablet nightly on retiring and to report for office treatment the first, third, and fifth day of the period for four periods. At this time the vagina is cleansed of blood and three Devegan tablets are inserted high in the vaginal vault. No douches are used. Her sexual partner must be examined by a prologist. It is

difficult to discover trichomonas in the male and often several examinations are necessary.

Thrush is the next common cause of vaginal itching or burning. Fortunately the treatment is short, effective and usually lasting. Two drams of sodium borate are dissolved in about one ounce of glycerine, and a tampon soaked with the solution is placed high in the vaginal vault. The treatments are given daily for 4 days. During pregnancy thrush does not respond readily to treatment.

Many women wipe themselves forward toward the vagina after a bowel movement with the result that the vagina and urinary tract may become infected with the colon bacillus. Contaminated water used for douching may also be a source. The diagnosis is made by smear and culture. The treatment has been simplified since the introduction of sulfonamides. Other types of bacterial infection seen as a cause of vaginal burning or itching are the taphylococcus, streptococcus, and the gonococcus. The infection responds to the sulfonamides, except that the gonococcus responds best to penicillin. In some cases of taphylococcus infection both sulfathiazole and penicillin may be used.

Vaginitis is occasionally seen following the use of caustic drugs, such as strong solutions of silver nitrate, zinc sulfate, or iodoform. When these drugs are discontinued the vagina clears up promptly as a rule. Some patients are allergic to dyes such as gentian violet or brilliant green, etc. The injection of a mild lubricating jelly helps to relieve the pain and prevents the mucous membranes from adhering.

In women past the menopause scaly vaginitis often produces itching, burning or both. The use of estrogen by mouth usually clears the vagina in less than a month. The physician must rule out external causes such as leucoderma and leucoplakia as well as trichophyton infection and lack of cleanliness. Pediculosis, scabies, and diabetes must be ruled out.

Rectal itching is a very distressing symptom and the diagnosis of the cause is often baffling. Amebiasis, or some other type of intestinal organism may cause irritation with or without diarrhea. Worms of various types are said to be the etiologic factor. The treatment of these patients is directed toward clearing up the bowel by appropriate medication to remove the amebic worms together with local treatment with gentian violet. The second common source is a fungus growth. The diagnosis is readily made clinically by painting the area with a 3 per cent to 5 per cent aqueous solution of gentian violet. In a few hours the itching ceases or is markedly relieved. The dye has to be carried into the anus a short distance because the fungus infection often extends to the mucous membrane.

JERRY R. WOLFF, M.D.

Employment of the Prone Position in the Treatment of Vesicovaginal Fistula (Sul trattamento bocconale delle fistole vesico-vaginali) MACACOS G B Arch Ital Med 947 14.

The author recognizes the successful operative results obtained in cases of vesicovaginal fistula and

cites the necessity for employment of the prone position in treating these patients. He describes 2 interesting cases of this condition.

The first was that of a 35 year old woman who developed a vesicovaginal fistula after her last delivery. Eight months after the onset she was operated upon under spinal anesthesia, according to Sims' method. Immediately following surgery she was placed in the prone position with a Pezzar catheter in the bladder which was irrigated with small amounts of sterile water. A few years later the patient developed uterine prolapse, for which an anterior colporrhaphy was performed. During this operation no traces of the former vesicovaginal fistula could be detected.

The second patient, age 28, having the same condition, was treated in a similar manner. Within 25 days the wound closed.

The author stresses the prone position to avoid contact of the urine with the wound. Insertion of the Pezzar catheter is insufficient for deviation of the urine from the wound. Certain surgeons go so far as to rely on the lateral or ventral position completely without inserting a catheter; however the author advocates the use of one. ANTHONY F. CIRIELLO, M.D.

Endometriosis Outside the Uterus (Endometriosia al di fuori do l'utero) CLOVIS CORREA DA COSTA J. Brasil G 948 25 7.

Eighteen years before she was seen by the author a woman of 43 years began to show some hard and painful nodules on the internal aspect of the thighs. During the week before menstruation the nodules became red and more painful and finally exuded blood. This coincided with or followed menstruation. The bleeding usually lasted 3 days and gave great relief to the patient who had a true dysmenorrhea. The bleeding recurred through the same site for 3 or more menstrual cycles until the nodule was replaced by a stellate scar. Then a new nodule formed back passed through the same phases. About 6 or 7 years before the author saw this patient similar nodules developed in the submammary folds on both sides, on the pectoral areas, and in the vicinity of the axillae. The woman had been operated upon 5 times and considerable amounts of bleeding tissue had been removed from the thighs.

At examination the author found on the internal aspect of the thighs a 4 in. vicinity of the breasts, old healed lesions with stellate scar and recent lesions consisting of small, hard, and infiltrated nodules of reddish color which raised the skin. These were painful and presented central perforations from which blood exuded spontaneously or under compression. The thighs showed 31 scars. Three or four foci were active in the thighs and more in the mammary region. There was a small myomatous nodule on the posterior surface of the uterus. A biopsy specimen from the thigh showed the typical picture of endometriosis.

The author had the chance to observe 2 other cases of endometriosis outside of the uterus but was not in

GYNECOLOGY

a position to obtain histologic confirmation of these conditions. One patient had a small nodule on the external aspect of the right thigh which increased in size became reddish and painful and bled at the time of menstruation. The other patient had a similar nodule in the palm of the left hand which became painful large and red and exuded blood during menstruation.

It is difficult to reconcile the metastatic theory of Halban and Sampson with the facts observed in the reported cases. Why would metastases have developed exclusively in the thighs so many years ago and have remained localized there for 6 years subsequent to invade the mammary region only? There is certainly no anatomic reason to justify the persistence of metastases solely at two points. The only possible explanation is the development of blastomeres and the subsequent formation of endometrium alone after all other potentialities have been lost.

RICHARD KRAVET, M D

The Treatment of Pelvic Endometriosis. HENRIK E. SCHMITZ and JAKOB E. TOWNSEN. *Am J Obst.*, 1948 55 583.

The treatment of pelvic endometriosis is either radical or conservative. The complete destruction or removal of all ovarian tissue results in regression of the ectopic endometriomas but inasmuch as most women suffering with this condition are in the child bearing period, this is a costly price to pay. Pelvic endometriosis is a major cause of sterility. Conservative treatment which will increase the possibility of conception is therefore the most desirable form of therapy. However individualization is necessary in each instance as the age of the patient her desire for offspring and the extent and location of the disease influence the decision as to the ideal treatment for that particular patient.

A review of 130 patients who were treated with this intent shows that 57 were treated surgically and of these 30 patients required radical surgery. Surgery is by far the most satisfactory form of treatment because it permits a careful inspection of the peritoneal cavity and microscopic confirmation of the diagnosis. Of those treated with conservative surgery 25 obtained complete relief and 9 of these subsequently became pregnant.

Röntgen therapy was employed in the treatment of 29 patients, 17 of whom were given sufficient dosage to cause a permanent menopause the others were treated with a smaller dosage causing a menopause of from 3 to 8 months. In this group 2 patients conceived and were delivered of 3 infants. Röntgen therapy in this group proved satisfactory as secondary therapy when conservative surgery had failed. Röntgen therapy of sufficient intensity to destroy ovarian function is indicated in cases in which endometrial tissue has invaded the bowel or bladder. It obviates the necessity of surgical resection with its increased risk.

Hormone therapy with androgens in young patients with minimal complaints not only corroborates the diagnosis when it subdues the symptoms, but it may enable the physician to carry his patient to an age when more radical treatment would not be so costly. It has been the authors' observation that some patients have pelvic endometriosis without discomfort and that other patients recover spontaneously.

Androgen therapy was used in 15 of the cases in the authors' series. These patients were young with minimal pathology, small nodes or single small cysts but with definite relationship to the menstrual cycle. One patient conceived during this treatment and delivered a normal infant.

JOHN R. WOLFE, M D

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

Observations on 14 Cases of Late Extrauterine Pregnancy
H. HUDNALL WARE, JR. *Am J Obst*
94:5, 55 56

Thirteen cases of extrauterine pregnancy of 28 weeks' duration (or longer) are presented, and 249 cases which have appeared in the literature since 1935 are reviewed. Twelve patients were operated upon. The maternal mortality, including a mother who left the hospital and died 3 months after operation, was 35 per cent. The maternal mortality for all 13 cases, including one woman who died undelivered, was 30.76 per cent.

A history of lower abdominal pain, from the onset of pregnancy or soon thereafter, accompanied by indigestion, constipation and sometimes irregular vaginal bleeding suggests an extrauterine pregnancy. The absence of uterine contractions when the fetus is palpated, a transverse or abnormal position of the fetus, a firm, long cervix, and a small empty uterus confirm the diagnosis. Roentgen examination of the abdomen and hysterosalpingograms were valuable aids in confirming the diagnosis.

An extrauterine fetus can remain viable and continue to grow after repeated episodes of uterine bleeding. Regular rhythmical uterine contractions were observed in a patient with an extrauterine pregnancy.

The treatment in each case must be individualized. The placenta should be left *in situ* and the abdomen closed without drainage whenever removal of the placenta may cause hemorrhage or damage to a vital organ. Removal of the placenta should be reserved for those cases in which the placental blood supply can be easily tied off and the placenta is not attached to a vital organ.

The placenta can be absorbed from its attachment in the peritoneal cavity without causing elevation of temperature or adhesions in the pelvic cavity.

When the placenta is left *in situ*, positive Friedman tests have been obtained on urine from the patient 35 days after operation.

The use of penicillin and sulfonamides may prevent or decrease infection in the placenta when it is attached to the intestine and left *in situ* and the abdomen is closed without drainage. Transfusions of whole blood and the use of new coagulants may be lifesaving measures in combating hemorrhage at the time of operation.

Plasma Proteins in Pregnancy J. L. MACARTHUR,
Am J Obst 94:5 55 58.

The author undertook to determine if a simple method of estimating plasma proteins could be adapted to routine use in office obstetrics and be sufficiently accurate to be clinically useful. Its application to a group of patients is described and dis-

cussed. A short reference to the physiological and clinical aspects of the plasma proteins is given.

Compared with plasma protein determinations by Kjeldahl analysis, the gravity method described, with an aqueous solution of copper sulfate, has proved to be accurate to within 0.3 gm. per 100 cc. The stability of the solutions and the rapidity and simplicity of the test make it ideal as an office procedure.

The hypoproteinemia of normal pregnancy is related to the plasma dilution. Combined hematocrit and plasma protein estimations give more information than the plasma proteins alone. The hypoproteinemia coincides with the increased plasma volume and in order to estimate the true level of plasma proteins the percentage of dilution should be added to show the plasma proteins well within the normal range.

After correction for plasma dilution, such normal levels have not been present in the patients with toxemia. In pre-eclampsia a difference of 30 per cent was found while in eclampsia the difference became more marked as the hematocrit levels rose, and the plasma proteins fell. The relationship between hematocrit and protein levels may prove to be a valuable diagnostic aid in toxemias; an increase in difference between them is a poor prognostic sign while a decrease in difference suggests improvement.

During the course of this study an attempt was made to evaluate the effects of supplementary feedings with protein hydrolysates by mouth and with normal patients and in those with toxemia. Over short periods of time no elevation of plasma proteins or improvement in the clinical condition of patient with toxemia of pregnancy was noted.

The hypoproteinemia of pre-eclampsia and eclampsia is very likely due to failure of albumin synthesis by a damaged liver. The essential amino acid methionine may, by its protective action upon the liver, materially aid in the prevention and treatment of toxemia of pregnancy. A case is presented to show dramatic changes in weight, edema, and clinical improvement of the patient after 5 days on the usual pre-eclamptic routine had failed.

The Puncture of the Amniotic Sac and the Amniocentesis (La ponction de l'amnios et l'amniocentèse).
L. FORTES and A. GRANTON. *Gyn Obst Pa* 94
47 4

Puncture of the amniotic sac through the abdominal wall has not received sufficient attention from the French obstetricians. This procedure must be harmless for the mother and the fetus. It can be done without undue trauma and without anesthesia. If a lumbar puncture needle and the Claude macometer are used.

Fig. 1 (Portes, Granjon) Fetus dead in utero. Amniography with tenetory. (Figure upside down on purpose.)

Fig. 2 Fetus dead in utero. The oocle has been intentionally inserted into the fetus. The spinal canal has been injected. Labor has not yet been induced. A second injection 48 hours later easily induced labor.

Fig. 3 Same patient as in Figure 1. (Film taken one hour later). The fluid injected into the amniotic sac is eliminated through the kidneys of the mother. The bladder is completely opaque.

The authors advocate aspiration of the amniotic fluid in cases of acute hydramnios which allows continuation of the pregnancy until the fetus is viable or the injection of normal saline solution to induce labor in cases with retention of a dead fetus in utero. Finally by the injection of opaque substances into the amniotic cavity the spontaneous and induced contractibility of the uterine wall may be studied under the fluoroscope. The placenta may be identified certain fetal malformities may be demonstrated and the passage of certain pharmacodynamic or hormonal substances through the placenta may be determined.

The authors have been able to demonstrate that only the distention of the amniotic sac can induce labor. The injection of the uterine muscle even injection into the dead fetus cannot incite contractions.

To induce labor in cases of retention of a dead fetus in utero the authors injected from 300 to 600 c.c. of normal saline solution the amount depending upon the age of the pregnancy.

GERARD GAONON M.D.

The Test of Labor with Breech Presentation in the Contracted Pelvis (L'épreuve du travail sur le col au cours des accouchements en présentation du siège dans les bassins rétrécis). RIVIÈRE, CHASTRUSSE, and MISON. *Rev. fr. gyn. obst.* 1947 42 303.

The poor prognosis in the delivery of a fetus in breech presentation through a contracted pelvis has long interested the authors. Under similar conditions with a vertex presentation a test of labor is justifiable in the majority of cases. Classically these

patients are brought to complete cervical dilatation and the possibility of delivery by the natural route is tested by the fetal head. With a breech presentation however this is considered unworkable illogical and dangerous. After a variable length of time following the engagement and descent of the breech the head (the principal obstacle) traverses the genital tract only when there is no other solution than to complete the extraction at any cost. Therefore cesarean section is carried out at the onset of labor.

Fig. 4. (Portes, Granjon) Pregnancy of 7 months. Huge hydramnios. Amniography with tenetory. Lateral view. Anencephalus.

The daily practice of allowing a test of labor in vertex presentations with contracted pelvis, results in vaginal delivery in 80 per cent of the patients. The indication for intervention comes in the majority of cases, not from an incompatibility of the cephalic and pelvic diameters as judged when dilatation is complete but from an anomaly of dilatation which failing to progress requires interruption of the test of labor and a hysterotomy.

By contrast, every obstetrician has had involuntary cases of spontaneous delivery of a fetus in pelvic presentation associated with a contracted pelvis in which the course of labor was so rapid that expulsion by the natural route had to be accepted.

An abnormal or irregular contraction is without effect on the dilatation and incapable of causing the fetus to progress even though there is only slight resistance to be overcome. The presence of an incompletely dilated cervix always renders extraction exhausting, dangerous for the mother and murderous for the child, even if the pelvis is but slightly contracted.

In contrast a rapid, brisk dilatation allows the doctor to hope that the powerful rhythmic contractions will help him at the moment of expulsion, and justify his expectation of delivery by the vaginal route.

The authors divided their experience into three periods. From 1936 to 1942 breech presentation complicating a contracted pelvis occurred 23 times and in 15 cases cesarean section was performed. Eight vaginal deliveries occurred because they could not be avoided. One malformed infant died following cesarean section and one normal baby died following extraction.

In 1943 and 1944 there were 16 such cases. Nine fetuses were delivered spontaneously, 3 were extracted and in 4 cases low cesarean section was performed. Three of the cesarean sections were performed for anomalies of dilatation.

During 1945 there were 6 patients whose labor was actively directed instead of passively assisted. This usually consisted of 3 units of "hypophyse" and spasmalgine although the routine was individualized. In one case it was necessary to resort to cesarean section.

On the basis of these experiences, the authors conclude that if severely contracted pelvis and very large babies are excluded the prognosis in breech presentation associated with a contracted pelvis depends on the type of labor. The "dynamic factors of labor" are the determining elements. The rhythm and intensity of the contractions, and the continuous progression of dilatation more so than its rapidity, lead to the successful outcome of a test of labor.

On the other hand cessation of dilatation should call for immediate cesarean section.

The authors conclude that the operative indications should be the same for breech presentation as for vertex presentation in the presence of a contracted pelvis. Regular progressive dilatation allows us to expect spontaneous delivery by the vaginal

route. On the contrary anomalies of dilatation usually require cesarean section.

CRAG W. MCKEL, M.D.

Pregnancy after Bilateral Salpingectomy; Concomitant Transitory Diabetes (Graviditas dopo salpingectomia bilaterale. Diabete transitorio concomitante). UGO SANTOMAURO, *Gior med Paterna*, 1947 41: 246.

The author reports the case of a young woman who had pain in the lower quadrants of her abdomen and in the lumbar region caused by an inflammatory process of the left adnexa. At operation most of the left ovary was removed, only a small portion corresponding to the hilus being left and the upper part of the right ovary which was studded with small cysts was excised. Bilateral salpingectomy was performed, a small subserosal fibromyoma of the posterior lateral left side of the uterine body was excised, and pelvic hysterectomy was done by fixation of a peritoneal flap from the vesicouterine fold to the posterior superior wall of the uterus. The patient had regular menstruations for one year and then, after a menstrual delay of about 30 days, spontaneous abortion occurred with delivery of an embryo 15 mm. in length. After another year she became pregnant again and had a spontaneous abortion in the third month. She took contraceptive measures for 4 years, then stopped them and became pregnant. During this pregnancy she developed diabetes for which she was treated adequately and the pregnancy continued to term when she gave spontaneous birth to a living child. After delivery the diabetes disappeared. She had 2 more pregnancies. In the first pregnancy the fetus died in the fifth month, the second ended in the eighth month with premature birth of a living child. During both pregnancies diabetes reappeared, and disappeared as previously.

How was it possible for the spermatozoon and the ovum to meet in view of the absence of the tubes, of which only small stumps were left and were covered by the vesicouterine flap when the hysterectomy was performed? To explain this it is necessary to accept that one or both tubal stumps had not been attached by the inflammatory process and that one or both cut ligatures had slipped, leaving the stumps free, or had been resorbed before compression necrosis of the tubal epithelium had occurred. The tubal epithelium must have proliferated and advanced from the resected face of the stump or through a new breach formed at the point of decubitus on the wall of the stump and made its way below the peritoneal flap which covered the stump until it reached the abdominal cavity thus making a true fistulous tract.

The author explains the diabetes as follows. As there was no sign of latent diabetes when the woman was not pregnant, she must have been in endocrine gland and sympathetic equilibrium. When pregnancy occurred, the influence of the hormones coming from the ovum caused a break in the functional equilibrium of the neuroendocrine apparatus manifested by the form of diabetes due to that type of

pancreatic insufficiency which according to Pende may perhaps depend on endocrine influences of non pathological nature in which it is not possible to demonstrate particular pancreatic lesions histologic ally

RICHARD KEMEL, M.D

Cancer and Pregnancy; Sarcoma of the Abdominal Wall with Various Recurrences Associated with Pregnancies (Cancer e gravidez. Sarcoma da parede abdominal com várias recidivas ligadas a gestações)
MÁRIO KROOK *Rev. brasil. cancerol.*, 1947 1 31

At the National Cancer Service in Brazil, clinical experience has created the impression that intercurrent pregnancy in a case of cancer aggravates the evolution of the tumor. For instance there was a case of apparently cured or arrested carcinoma of the maxillary sinus which developed rapidly after the first month of pregnancy similarly, a case of ulcerated sarcoma of the forearm healed by roentgen therapy became aggravated in a few days when the patient became pregnant. The following case is even more conclusive

The patient at the age of 25 developed a sarcoma of the anterior abdominal wall in February 1937 when she was 6 months pregnant. She stated that in infancy she had had an abscess at the same site which left a yellow reddish nodule as residue, that she was a weaver and that the nodule had been traumatized repeatedly by a spring of the loom at which she worked. The tumor was excised 3 months after delivery. However in June, 1938 when she was 2 months pregnant she noticed at one of the extremities of the surgical scar a nodule which grew from the size of an almond to that of a large orange in 2 months. When referred to the Cancer Center she presented in the umbilical region a round tumor the size of a fetal head and ulcerated over the greatest part of its surface. The tumor was diagnosed as a fibromyxosarcoma and removed. The pregnancy continued to term. The tumor recurred and was again excised in 1939, 1940, 1943 and 1946 each time during a pregnancy. Thus in 6 years from February 1937 to March, 1943 this patient had 5 bouts of sarcoma in association with 5 pregnancies. Then she decided to use contraceptive measures and there for 3 years she did not become pregnant and there was no recurrence of the sarcoma but when she neglected the contraceptive precautions and again became pregnant she developed the sixth attack of sarcoma in January 1946. The relationship between cancer and pregnancy became so evident to the patient that cicatricial pruritus constituted for her the best index to her genital condition. The 6 pregnancies resulted in 3 deliveries at term and 3 abortions.

Treatment of the various recurrences has kept the patient in a state of apparent cure for more than 10 years. The tumors of varying sizes were removed without ventration by the method of electrothermal coagulation sometimes during the pregnancy. Roentgen therapy was used once and resulted in radionecrosis without disappearance of the lesion.

This treatment was applied to the abdominal wall during a 4 months pregnancy in a dosage of 4 600 roentgens over 30 days. It did not cause abortion or sterilization of the patient but it must be admitted that the irradiations were given tangentially and that the uterus was below the level of the irradiated zone.

The following problems arise with the admission of the noxious effect of pregnancy on the evolution of cancer. Should patients with cancer of the breast, or those who have been operated upon for cancer nurse their children? Does nursing help to transmit susceptibility to cancer from mother to child and from nurse to nursing? Should patients operated upon for cancer of the breast, even after a 5 year cure get married? Should they become pregnant? If pregnant should they be subjected to abortion? Should roentgen castration be performed routinely in all patients with breast cancer whether operated upon or not?

RICHARD KEMEL, M.D

MISCELLANEOUS

Medical Report for the Year 1946
GARREY and J. T. SWAN BROWN
Maternity and Women's Hospital

MATTHEW M.
Glasgow Royal

A report from the Glasgow Royal Maternity and Women's Hospital (a 168 bed hospital) for the year 1946 gives a total admission of 4 643 patients.

There were 3 347 births. Of these 3 062 were live births and 285 were stillbirths. There were 171 neonatal deaths giving a fetal mortality of 4.56 or 13 per cent.

The maternal mortality was 47 or 1.01 per cent. Two hundred and sixty-six cesarean sections were performed an incidence of approximately 8 per cent. Of these 147 were classical procedures with 4 deaths (2.7%) and 119 were low cervical sections with no deaths. The gross maternal mortality for the whole series was 1.5 per cent.

The whole series of 3 347 births is broken down in to abnormal presentations hemorrhage antepartum and postpartum toxemia disproportion and sepsis with a detailed description of each case in the above categories.

It is unfortunate that there does not exist a universal, standard form with a common terminology for obstetrical reports of this type. Such a form would clarify the information contained in the report and would eliminate the detailed description of individual cases.

CHESTER C. DOHERTY M.D

Chorioepithelioma of the Uterus with Vaginal Metastasis (Córionepitelioma do útero com metástase vaginal)
RANCI MENDONÇA OLIVEIRA and JAMIL DAUD
An. dist. gls. fac. med. Univ. S. Paulo 1947 p 57

The authors present 2 cases of chorioepithelioma in women of 24 and 52 years, respectively in both the metastasis consisted of a soft dark red nodule the size of a nut, which bled easily when touched. In the first case the nodule was located in the vulvar vestibule just below the urethral meatus, in the second it was in the anterior vaginal wall on the

median line and about 4 cm. from the urethral meatus. Hysterectomy bilateral adnexectomy and excision of the nodule were performed in both patients with apparently good results.

Chorioepithelioma, which is very malignant and leads to early metastasis, is a rare tumor that generally develops in the area of ovular implantation and may occur after normal delivery, abortion, or hydatiform mole. In the first case it occurred after an abortion in the second it was preceded by a hydatiform mole. It seems that the incidence of chorioepithelioma following hydatiform mole is between 6 and 10 per cent. The average age at which the tumor occurs has been estimated at 34 years. The tumor is found more frequently in multiparas than in primiparas in the first case the patient was a primipara and in the second a multipara with 12 deliveries at term.

Macroscopically the tumor has a nodular form, is polypous or infiltrating, has a hemorrhagic aspect and a dark red color and is very friable. It invades the uterine wall, destroys the walls of the vessels, and throws trophoblastic cells into the circulation, thus it initiates metastases at points remote from the primary tumor. The histologic picture is characterized by the presence of columns or alveoli of trophoblastic cells separated by spaces full of coagulated blood in which occasionally chorionic villousities in a state of regression may be found.

Retrograde metastasis to the vagina and vulva in the form of nodules of varying sizes is frequently observed in uterine chorioepithelioma, these metastases resemble hematomas or angiomas. Vaginal metastasis is frequent but less frequent than pulmonary metastasis. The latter was absent in the 2 reported cases. The finding of vaginal metastases in these cases suggested the possible presence of chorio-

epithelioma, and biopsy of the nodules confirmed the correctness of the suspicion. It is to be noted that in the first case recurrence of the nodule at the same site was nearly immediate after extirpation which was done elsewhere.

The diagnosis may be made clinically or biologically. The clinical diagnosis is based on the symptomatic triad of uterine chorioepithelioma: recurring metrorrhagia, a fetid discharge due to necrosis of the tumor and temperature indicating infection and vascular thrombosis. The tumor is asymptomatic when it is intramural. However these symptoms are not always present in characteristic form, chiefly in incipient cases. The biologic diagnosis is based on the fact that the pregnancy test becomes negative 1 to 4 weeks after delivery or abortion and 1 month after evacuation of a hydatiform mole. Persistence of a positive test after evacuation of the mole has in itself no great significance as long as the titer decreases or remains stationary; but an increase in titer must be carefully watched. There are also cases of negative reaction in the presence of chorioepithelioma.

The prognosis is poor, from 70 to 80 per cent of the cases are fatal. However periodic determination of the amount of hormones in the blood of women who have expelled a hydatiform mole may reveal the beginning of the development of chorioepithelioma, and allow the institution of early and radical treatment. The period for which these women must be watched is at least one year. Regression and spontaneous cure of the primary tumor and its metastases are possible. The course of both reported cases was satisfactory 10 and 4 months, respectively after the operation. The authors believe that early operation offers the best chance for cure.

RICHARD KIDDER, M.D.

GENITOURINARY SURGERY

ADRENAL, KIDNEY AND URETER

Two Cases of Arterial Hypertension Treated Surgically (Dois casos de hipertensão arterial tratados cirúrgicamente) L. DE MORAIS ZAMITH. *Rev Port Obst gín. cir* 1948, 1 29

Two cases of unilateral hydronephrosis accompanied by arterial hypertension are reported by the author

In a man 23 years of age the hydronephrosis showed signs of infection and was responsible for fever and painful phenomena. Roentgenographic studies showed absence of renal or ureteral calculi while ascending pyelography demonstrated an obstruction in the ureter. Decapsulation of the involved kidney and elimination of the angulation of the ureter caused by adhesions was followed by a return of the arterial pressure to the normal level

In a woman 36 years of age the hydronephrosis possibly of congenital origin, had been of a silent nature until the patient reached the age of 31 years when signs of hypertension appeared. Left hydronephrosis was discovered in roentgenograms and a nephrectomy was performed. The pathologic examination showed chronic interstitial nephritis with arteriosclerosis. Remarkable amelioration occurred but did not last more than a few weeks and the blood pressure gradually reached the preoperative level. Probably similar changes were present in the other kidney and possibly in the entire arterial system. This case demonstrated the necessity of close collaboration between the cardiologist and the urologist for the purpose of early detection and elimination of hypertension of obscure origin.

In the first case the formation of the hormone renin was probably conditioned by the disturbance of the equilibrium between the arterial pressure and the pressure of the filtrate in the glomeruli. Renin determines the formation of the peptide hypertension which plays a great role in arteriospasm. After the re-establishment of the equilibrium between the arterial pressure and the pressure of the filtrate in the glomeruli after the operation no more renin was formed

JOSEPH K. NARAY, M.D.

Renal Complications of Hyperparathyroidism. EDGAR BURTON and C. MARK WHITEHEAD. *J Urol* Balt., 1948 59 664

Although more than 330 cases of hyperparathyroidism have been recorded to date, the disease is a relatively rare one. The incidence being probably no more than 1 in each 1,500 hospital admissions. The authors report 4 additional cases from the Ochsner Clinic, New Orleans, Louisiana. The parathyroid adenoma is a benign lesion but from the standpoint of endocrinology it is an active tumor causing metabolic disturbances which increase the serum calcium and lower the serum phosphorus concentrations.

Both calcium and phosphorus are excreted in abnormally large amounts in the urine.

The kidneys may be involved in three ways. In the first there is a formation of calcium phosphate stones in the pelvis with secondary pyelonephritis. In the third there is an acute parathyroid poisoning with anuria and death with calcium deposits in the renal parenchyma but without chronic renal changes. In the second there is an intermediate condition simulating both glomerular and vascular nephritis.

Hyperparathyroidism should be considered in every case of renal calculi. Surgical removal of the parathyroid adenoma is the only effective treatment. Except in acute conditions of the urinary tract such as ureteral block the parathyroid tumor should be removed first. Results of roentgen therapy have been disappointing.

JOSEPH E. MAURER, M.D.

Hemorrhage into Parenchymal Lesions of the Kidney LEON HERMAN. *J Urol* Balt. 1948, 59 544

Herman reports 2 cases of patients in whom massive spontaneous hemorrhage into and around parenchymal lesions of the kidney occurred.

In the first case massive spontaneous hemorrhage into and around a large renal lipoma caused severe pain and the sudden development of a large mass in the loin. In renal lipomatosis, the diseased parenchyma is replaced by hilar fat until merely a thin peripheral layer of uninvolved kidney tissue remains. Renal stones frequently are associated. The first patient had a large tender mass which filled the loin space and extended to the midabdominal line and midway between the umbilicus and inguinal canal. The overlying muscles were rigid and the umbilicus and surrounding tissues were infiltrated with dark blood. At operation the kidney tumor mass resembled a hypernephroma with spontaneous rupture due to intratumoral bleeding. The pathologist reported an intrarenal lipoma growing possibly from the peripelvic fat originally but finally impinging upon and compressing and distorting the renal parenchyma of the lower pole. The second patient had a congenital single kidney multiple cysts, and intracystic hemorrhage which caused ureteral compression with anuria. Evacuation of clots from the cyst resulted in prompt filling of the ureter and spontaneous emptying of the pelvis.

DAVID ROSENBLUM, M.D.

Clear-Cell Tumors of the Kidney (Tumores del tipo a células claras) JOSÉ MARIA MAINETTI. *Rev med hosp Ital La Plata* 1947 4 27

Four cases of Grawitz hypernephroid tumors of the kidney are reported. The patients were 3 males and one female all adults and in all the tumor was on the left side. The usual symptoms were hematuria, renal colic, loss of weight and strength as well as the other symptoms and signs of renal tumor. At operation in one case the tumor was found to be so

adherent to the elevated and widely spread left colic flexure that a colectomy was done with the production of a temporary artificial anus. In this case, also, there were adhesions to the muscles of the back, and the pedicle of the involved kidney contained huge arterial branches; nevertheless the operation was successfully completed and the patient recovered began to put on weight and gain in strength. The artificial anus was later suppressed by cutting through the dividing spur between the two colonic loops, and the opening in the abdomen at this point was closed entirely within 30 days.

The author believes that the theory of origin of these Grawitz tumors from embryonic inclusions of suprarenal cortical tissue within the kidney has been pretty well disproved. He believes that they arise from the tissues of the kidney itself. Whatever their origin, however, they are the most common tumor of the kidney in adult life and their malignancy is undisputed. When the descending pyelographic examination discloses defective or absent kidney function the author thinks that it denotes tumor-cell thrombotic obstruction of the renal veins. The veins should then be carefully examined as far as the vena cava and extirpated or the thrombi extracted, a recommendation by Beer. JOSE W. HANCOCK, M.D.

Renal Decapsulation for Anuria. LEVINO J. SHAPIRO
J. Urol. Balt. 94:3, pp. 336.

The author states that one must not temporize in the treatment of anuria which is due to the toxic action of the sulfonamides. Cystoscopy and ureteral catheterization should be carried out promptly to determine whether crystals are a causative factor and even if these are absent pelvic lavage with bicarbonate solution should be performed. If anuria is not relieved bilateral renal decapsulation should be performed without delay. A slight increase in elevated intrarenal pressure may play a part in the production of anuria.

In both cases cited by Shapiro a waterlogged condition of all the tissues was strikingly noticeable at operation. When large amounts of fluid intra-venously are administered in anuria the fluid, instead of being excreted by the kidneys is deposited in all the tissues of the body and the amount retained by the renal interstitial tissue further augments the intrarenal pressure compressing the blood supply and tubules to such an extent that the process can only be reversed by the relief of this increased tension through decapsulation. Pulmonary edema and cardiac decompensation may occur if larger amount of fluid are given than can be excreted by perspiration and by the bowel and lung.

Two cases are reported in which anuria due to sulfathiazole was relieved promptly after bilateral renal decapsulation. D. VID ROSENBLUM, M.D.

Physiology of Intact Human Ureter. JACK LARSEN
J. Urol. Balt. 94:3, pp. 50.

It is postulated that tonic and rhythmic contraction of the intact human ureter are entirely inde-

pendent of the central nervous system including the autonomic nervous system and all its ganglia.

The normal adequate stimulus for the initiation and maintenance of ureteral peristalsis is a stretching of the smooth muscle fibers of the ureter by the urine excreted from the kidney.

Peristaltic activity of the ureter can be altered by changes in urine volume output, within certain limits.

Rhythmic contractions and tonus of the intact human ureter were not directly affected by the administration of tetracetylaminonium chloride, procaine, high spinal anesthesia, doryl, epinephrine, prostigmine, atropine, trasecillin, amethone, depropoxy, calcium levallinate, nitroglycerine, amylnitrite, papaverine, perparin, lipolutin, pitressin, avertin (intrauterally), benadryl, demerol, and morphine.

Demerol, pitressin, and large doses of epinephrine produced a decrease in urine secretion.

Prostigmine acted as a diuretic in one-half of the patients in whom the drug had been administered.

No drug depressed ureteral peristalsis or decreased the tonus of the ureter. Morphine does not produce increased peristalsis and tonicity of the ureter.

JOHN A. LOER, M.D.

Reconstruction of Ureter with Bladder Flap. ROGEE W. BARNES and STANLEY F. RILEY
J. Urol. Balt. 94:3, pp. 466.

The authors review the literature and describe a method of reconstruction of the ureter with a bladder flap which they used on experimental animal with the following results:

The 6 calves were operated upon. One died under anesthesia. 6 died in less than 1 month. 4 lived 1 month or longer. In each case the tube made from the bladder flap remained viable. There was no sloughing of tissue of the reconstructed ureter in any case.

In the 6 calves that lived less than 1 month after surgery there were 3 in which the reconstructed ureter did not function properly. In one animal this was due to lack of a ureteral catheter as a splint, with resulting occlusion at the site of anastomosis. In the other 2 calves, urinary extravasation occurred due to a faulty technique in suturing and the difficulty of keeping ureteral catheters in place.

Of the 4 calves that lived 1 month or longer, only one had a stricture at the site of anastomosis, resulting in hydronephrosis and hydroureter. It is probable that this could have been avoided had the suture line been made diagonal rather than circular, which would have eliminated a circular scar around the ureter at one level. One other calf developed intestinal obstruction due to leakage of urine with localized peritonitis.

One calf lived 12 months after operation and was sacrificed. At autopsy no evidence was found of ureteral stricture, hydronephrosis, or hydroureter.

The difficulty of keeping ureteral catheters in place and of keeping urethral or cystostomy tubes draining in these calves added greatly to the mor-

talities. The unusual susceptibility of the calves to infection and operative trauma was also a cause of increased mortality. When this type of surgery is performed on humans, these difficulties are easily overcome by proper after care. There was no difficulty in obtaining a viable flap that would reach two-thirds of the distance to the kidney.

JOHN A. LOER, M.D.

The Management of the Surgically Traumatized Ureter THOMAS D. MOORE, *J. Urol. Balt.* 1948, 59: 712

Accidental injury of the ureter during the course of pelvic operation is not uncommon. This type of serious accident has a mortality rate of 33.3 per cent for bilateral ureteral injuries and 18.8 per cent for the unilateral injuries. In difficult hysterectomies and in removal of intraligamentous tumors and cysts when the normal course of the ureter may be distorted it may be unsuspectingly injured. The incidence of such accidents may be difficult to determine because unilateral injury may be entirely unrecognized particularly if simple ligation of the ureter has occurred.

The incidence of ureteral ligation as a complication of all operations on the female genital organs may be placed at between 1 and 3 per cent. Many cases are not reported and many may not be recognized. The proportion of unilateral to bilateral injury is 6 to 1. The most common sequelae of ureteral injury are ureterovaginal and ureteroabdominal urinary fistulas.

Injury of the ureter may occur at the hands of the most skilled surgeon. Urologists believe that such injuries are preventable. They have advocated the preoperative insertion of indwelling ureteral catheters when difficult pelvic surgery is anticipated. These indwelling catheters can serve as a guide so that the ureter can be more easily recognized and avoided. However, many gynecologists are loathe to accept this precautionary measure. They contend that the catheters give a false sense of security and alter the normal position of the ureters making the ureter more liable to injury. In many instances the catheters cannot be located by palpation and can give rise to infection, ureteral colic, and oliguria. There is an abundance of evidence indicating that in spite of these objections the preliminary insertion of ureteral catheters is a wise precautionary measure. Accidental injury to the ureter can be divided into two types: (1) that in which the injury is recognized immediately and (2) that which is discovered in the postoperative period. Both types can be subdivided into unilateral and bilateral ureteral injuries. The types of injury are ligation, occlusion by acute angulation from sutures placed near the ureter, crushing or clamping, incision without severance, crush and resection of a portion of the ureter.

The simple ligation of one ureter seldom is recognized at the time of operation. If the accident is discovered during the operation, immediate deligation followed by the insertion of a ureteral catheter would

be adequate treatment. Crushing by a clamp requires essentially the same treatment as a severed ureter because of the probability of subsequent sloughing or dense cicatricial contracture. There are several procedures that may be adopted to repair this type of accident. End-to-end anastomosis has proved more satisfactory than end-to-end anastomosis of the injured ureter. A small opening above the anastomosis through which the ureteral catheter is passed to the renal pelvis and brought out of the flank for temporary diversion of the urinary stream has been advocated following the repair of this type of injury. The author warns that although the immediate results of this type of repair may be good the patient may require frequent and systematic dilations of the ureter otherwise, slow hydro-nephrotic atrophy may necessitate late nephrectomy. If the ureter is injured low in the pelvis an attempt can be made to anastomose the ureter to the bladder.

Cutaneous ureterostomy is mentioned only for condemnation although this procedure may be regarded at the time as a conservative procedure. Although ureterointestinal anastomosis may seem a good procedure few patients are prepared for this type of surgery as the risk would be greater than in a planned operation of this type. Ligation may be the operation of choice, especially after a difficult and long operation and if the patient's condition is considered to be poor. Before ligation of the proximal stump of the ureter it is wise to palpate the opposite kidney to determine its condition. If the extreme condition of the patient prohibits conservative measures temporary measures less radical than ligation of the ureter, nephrectomy or cutaneous ureterostomy would permit a conservative operation at a later date: (1) the passage of a ureteral catheter through the proximal segment of the severed ureter; (2) temporary ureterostomy and (3) temporary nephrostomy may permit conservative surgery at a later date.

In many cases the appearance of the urinary drainage from the vagina or the abdominal incision in the early postoperative convalescence of the patient is the first evidence of ureteral injury either unilateral or bilateral. If both ureters have been ligated or otherwise occluded, the case may be erroneously diagnosed as suppression of urine. Failure to demonstrate urine in the bladder from 6 to 12 hours following a difficult pelvic operation renders a cystoscopic examination to determine the patency of the ureters as mandatory for too often the patient will be treated for suppression of urine for days before the true nature of the condition is suspected. If cystoscopic examination confirms the suspicion of bilateral ureteral occlusion, an immediate unilateral nephrostomy may prove a lifesaving measure. Temporary ureterostomy may be preferred to bilateral nephrostomy because it is technically easier to do. Deligation of the ureter is extremely hazardous and difficult. If it is attempted by the surgeon, the aid of the urologist should be elicited to literally prod the

obstructed points with a large caliber catheter (9 or 11 F) from below. This procedure would permit the surgeon to clip the ligatures quickly and recognize more than one ligated point if present. The ureteral catheters should then be passed into the renal pelvis.

The author presents 4 illustrative cases with pyelographic demonstrations showing the varied methods adapted to the management of the cases present.

In conclusion, the principal management of surgical injury to the ureter is determined by the early or late discovery of the injury and the nature and site of the accident. In instances of complete anuria following extensive pelvic surgery the possibility of bilateral occlusion of the ureters should be considered and cystoscopic examination should be done to determine the patency of the ureters. Diligation of the ureters is a hazardous and difficult procedure. The urologist may be able to demonstrate the point of ureteral ligation when the abdomen is reopened and make the procedure far safer. When the ureter has been severed or damaged, sacrifice of the involved kidney by ligation or nephrectomy is to be condemned except under the most urgent circumstances.

COSMAD A. KURKCH, M.D.

Proliferative Tumors of Ureter DUDLEY P. FAULKNER. *J. Urol. Balt.*, 1943, 59: 333.

Interest in proliferative lesions of the urinary epithelium has increased tremendously over recent years. Such growths have been shown to be of much more frequent occurrence than was formerly suspected.

The primary interest in this study concerns the debatable role played by epithelial nests in the etiology of solid and cystic proliferations of the ureter and renal pelvis, with only casual reference to similar growths of the bladder mucosa.

The conflicting views as found in the literature relating to epithelial crypts, buds, and nests are briefly presented.

A microscopic investigation of 120 ureters removed at autopsy has been carried out in order to study these epithelial aberrancies in their incipient stage, and to determine their etiologic significance in solid and cystic tumors of the ureteral mucosa.

Six clinical cases presenting various types of mucosal neoplasms are discussed; the microscopic findings and the surgical specimens have been correlated with the epithelial changes found in the series in which autopsies were performed.

The author concludes that hyperplasia of the urinary epithelium may result from local irritation such as chronic infection, or from noxious agents circulating in the body fluids.

Epithelial buds and crypts are but bizarre expressions of epithelial hyperplasia. The theory of "cell nest" formation as proposed by von Brunn and accepted by most present day writers is not supported by this study.

Cystic tumors of the ureteral epithelium derive from occluded mucosal crypts, whose lining cells exercise a latent secretory potentiality.

No evidence was developed that solid epithelial buds are directly associated with the origin of solid tumors of the urinary epithelium.

Twenty-one figures illustrate the important facts supporting the author's conception of the origin of these tumors.

JOHN E. KIRKPATRICK, M.D.

BLADDER, URETHRA, AND PENIS

The Usefulness of Immediate Post Traumatic Urethrocytograms for Diagnosis of Rupture of the Bladder (Utilité des uréthrocystographies immédiates post traumatiques pour le diagnostic des ruptures de la vessie) L. SABADINI. *Presse méd.* 943, No. 9: 23.

The author observed a number of traumas to the kidney urethra, and the bladder over a period of 3 years. It was his practice to examine roentgenologically every case of contusion of these organs. He observed 15 contusions of the kidney in less than a month. Immediate pyelography permitted him to recognize the intrarenal and extrarenal lesions.

In a series of 50 traumatic ruptures of the urethra, urethrograms gave him very useful information.

Sabadini advocates the use of urethrocytograms in traumatic rupture of the bladder. His method is to obtain an x ray immediately following the accident to determine if the pelvis has been fractured. He then obtains a urethrocytogram with the patient in a slight Trendelenburg position. He uses Ipiodol—40 parts to 100—diluted with two-thirds oil of poplar—10 parts to 100. Following the injection of the solution the pictures are taken with the patient on his back slightly turned.

Three possibilities present themselves. The fracture of the pelvis may occur without any lesion of the inferior urinary tract. The urethra is normal throughout its length. The bladder appears regular in outline. In the course of the trauma to the pelvis, the bladder although not injured, is elevated and takes the shape of an oval balloon. This modification of the vesical shape is explained by pelvic hemorrhage accompanying the fracture of the pelvis, which causes the elevation, obstruction, and spreading out of the bladder.

In the rupture of the membranous urethra, the contrast media is arrested at the level of the injury and diffuses throughout the perineum. There is a cystogram of the bladder in these cases.

When the urethra is not injured and appears normal throughout its length but the bladder is involved, 3 types of pictures may be obtained. The most frequent type shows the obvious modification of the bladder morphology on injection of the contrast media. In rarer cases, the picture obtained gives information on the integrity of the urethra, but the bladder outline is not normal. The immediate injection of contrast media is pushed without fear. The bladder outline stands out and the lesion is apparent.

The average traumatic lesion causes the bladder to be elongated—pear-shaped—extending high in the pelvis in the midline, large, high, and rounded.

with an elongated bladder neck. The compression and elevation of the bladder is caused by the effusion of blood and edema about the large mass of liquid in the bladder. The perforation is apparent from the pictures. If it is in the base (paravesical), the contrast media diffuses about the bladder neck.

If the rupture is high and posterior the picture is that of a diverticulum on the posterior superior aspect of the bladder. The contrast media is blocked by perivesical edema and the intact peritoneum. In examining this picture, the question arises as to whether there is an intraperitoneal communication with the bladder. In perforations at the base, the peritoneum is not involved. In the high posterior perforations, it is necessary to explore the peritoneal cavity by operation to obtain information as to whether the rupture has extended into the peritoneum. In the extensive type of bladder rupture the most important sign is the wide diffusion of the contrast media which is 'archaic' and nonlimited. If the peritoneum is not ruptured the bladder fills it is soft and flaccid without reaction, and the contrast media descends into the base of the pelvis. When the peritoneum also is ruptured the contrast media transgresses the elongated urethra, is injected into the stump of the bladder and diffuses extensively throughout the pelvis and the peritoneal cavity as well as the iliac fossa. The liquid oil is seen swimming above the bloody urine in the peritoneal cavity.

The author outlines the roentgenological signs for rupture of the bladder. The direct signs are a diverticulum superimposed on an elongated high bladder, an elongated bladder neck, and the pear-shaped bladder suggesting the usual type of vesical rupture. When there are signs of massive effusion of the contrast media from the pelvis, and occasionally into the peritoneal cavity or diffusion into the bas-fond of the pelvis with a flaccid bladder extensive vesical rupture is present. The indirect signs are elongation of the bladder neck and elongation and erection of the bladder (like a banana, pear or child's balloon). This type of picture suggests to the author a limited parietal lesion. In brief the morphological modification of the bladder outline and the bladder neck caused by the large overflow of bloody urine associated with spasm of the vesical detrusor along with the signs of pelvic diffusion of the contrast media, are the x ray signs of probable vesical rupture. The positive signs of intraperitoneal rupture are massive diffusion of the contrast media spreading into and throughout the peritoneal cavity. The formation of a diverticulum of contrast media in the superior posterior portion of the bladder suggests intraperitoneal vesical rupture and demands careful surgical exploration.

In résumé, the author advises immediate cystourethrography following bladder rupture. The roentgenograms give valuable information as to the site of the vesical rupture and its extent and whether the injury is intraperitoneal or extraperitoneal.

CONRAD A. KUTZNER, M.D.

Plastic Operations on the Neck of the Bladder for the Cure of Incontinence in Complete Epispadias (Plastica del collo vescicale per la cura dell'incontinenza in soggetto con epispadia completa) RO-BARTO FERRACCIARO *Arch. Ital. urol.* 1947 22 106

Several methods used in the treatment of complete epispadias employ modified techniques. Their disadvantage lies in the fact that they cause irreparable cicatricial alterations and furnish poor esthetic results from the sexual point of view a nonerectile organ results and finally the incontinence cannot completely be controlled.

In a 13 year-old boy with complete suprapubic epispadias, the author employed the following procedure.

The urinary bladder was exposed with a long median incision and the pubovesical ligament was severed in order to visualize the lower portion of the bladder. This lower vesicourethral portion was placed in a longitudinal direction by means of two 'u' shaped sutures placed in a transverse direction.

The patient regained the ability of voluntary micturition and the frequency and quantity of the urine became normal. The amount of residual urine did not exceed between 6 and 7 c.c. Postoperative roentgen ray examination showed a satisfactory reconstruction. Nocturnal incontinence was completely eliminated, and diurnal incontinence was improved.

ANTONIO F. CROCELLA, M.D.

Multiple Vesical Tumors Characteristic of Hypernephroma (Eccellente tumore multiplo vescicale a caratteristiche ipernefroidi) ROBERTO CACCINI *Arch. Ital. urol.* 1947 22 69.

A patient 47 years of age had multiple vesical tumors in which the structure was not that of the bladder this caused difficulty in the interpretation of the genesis of the tumors.

The cellular elements constituting the neoplastic parenchyma had a resemblance to the cells of the suprarenal cortex. Aberrant germ cells of the suprarenal gland were considered to be the origin of these tumors. Each tumor was identified as an endothelioma thus, the author hypothesizes the tumor may have had its origin from embryological epithelium.

Cystoscopic examination on this patient revealed neoformations of various sizes ranging from a large pea to a hazelnut on the dome and lateral surface of the bladder. Each of the six neoformations appeared distinct from the others, and was definitely not similar to the common papilloma. A biopsy revealed the tumors to be composed of specialized epithelium.

The patient was operated upon and the bladder wall covering the area of the tumors was excised. Previous to the bladder repair a Pezzer catheter was introduced. A tubular drain and iodoform gauze was placed in the space of Retzius.

Gross examination revealed the tumors to be of a meaty to deep red color in contrast to the pallid cells of the bladder mucosa. All the tumors were

acmille, without any apparent infiltration of the base. Histological examination revealed a mass of polyhedral cells abundant with protoplasm. The nuclei were round, situated in the center but often they were shriveled and displaced to the periphery. Some cells had double nuclei. In some areas there was abundant vascularization with capillaries and precapillaries filled with blood among the mass of cells. Dimensions of the cells varied from 6 to 7 microns to from 18 to 20 microns. Not a single section was similar histologically to the normal bladder. Although not encapsulated the cells were well limited they occupied the submucosa with a distinct line of demarcation at the premuscular connective tissue.

ARTHUR F. CITOLLA, M.D.

Penoscrotal Hypospadias. JORGE R. ILAND. *J Urol* Balt., 1948, 59: 414.

The author describes a three stage operation for the repair of hypospadias. An incision is made just below and along the ventral base of the glans. All constricting fibrous tissue which includes remnants of the corpus spongiosum, is carefully dissected away. The foreskin is then incised around the glans and a transverse buttonhole is then made in the foreskin, as suggested by Nesbitt. The foreskin flap is pulled over the glans and allowed to drop down like an apron over the denuded area on the ventral aspect of the penis. It is fixed in place with interrupted No. 000 catgut sutures.

At the second stage the pendulous urethra is reconstructed according to the method of Duplay. The urethral tube is then rotated and anchored with silk sutures to prevent an overlapping of the urethral and cutaneous suture lines.

At the third stage the perineal meatus is closed over a 14 F catheter which is either removed or left in situ for 24 hours.

The sutures are placed over rubber tubes on either side of the perineal closure to support the suture line.

In the case reported there was an interval of 15 months between the first and second stages and 9 months between the second and third stages.

The urine is not diverted.

FREDERICK A. LLOYD, M.D.

Repair of Hypospadias. DONALD R. SMITH AND HARRY M. BLACKFIELD. *J Urol* Balt., 1948, 59: 404.

Although the hypospadiac penis presents a penile and urethral defect, the relatively gross techniques of urologic surgery cannot properly be applied to its repair. It is a problem in reconstruction, and the fundamental principles of plastic surgery should be utilized.

A proper result must above all, afford a straight penis. The urethra must not terminate posterior to the base of the glans, and its caliber should be of such dimensions that urethral dilations are unnecessary after its construction. The principles of plastic surgery involved include the use of skin flaps

with broad bases to insure adequate blood supply, the gentle handling of tissues, careful hemostasis, lack of tension upon suture lines, the application of pressure dressings to insure proper approximation when skin flaps are used, the use of fine suture material and the absence of juxtaposition of the suture lines of the newly constructed urethra and of the covering skin flap.

The authors employed the operation of Vilray Blais. They have modified the second and third stages to simplify the procedure.

At the first stage the skin is dissected widely from the ventrum of the penis so that complete removal of fibrous bands can be accomplished. Preputial skin is then swung onto the ventrum whose area has been increased by the correction of the chordee. At the second operation a pendulous urethra of generous caliber is formed after the method of Duplay. It is constructed down to a point just distal to the hypospadiac orifice and the denuded ventrum is covered by a flap of scrotal skin whose base is left attached to the scrotum. The final procedure allows of the freeing of the penis from the scrotum, and the proximal end of the new urethra is anastomosed to the abnormal urinary meatus.

The correction of the chordee should be performed when the boy is about 18 months of age so that the corpora cavernosa will develop normally. The second stage is performed when the patient is 4½ years old and the final step before he is 5.

FREDERICK A. LLOYD, M.D.

Radiation in Peyronie's Disease. ROBERT E. FRICKS AND JAMES H. VARNET. *J Urol* Balt., 1948, 59: 637.

Fibrous plaque of the penis disturbs no vital function and is not a serious condition, however it tends to cause severe mental distress and every effort should be made to cure the condition. Usually the disease occurs in middle-aged patients. It appears to be a self-limiting process. Although formerly this was considered an extremely rare disease many more cases have been reported in recent years.

The etiology is not known. Microscopic examination of excised fibrous plaques presents a picture resembling that of keloids elsewhere in the body. Hence trauma due to previous infections, passage of sounds, or some other factor may well be the cause.

Although the present methods of treating Peyronie's disease are unsatisfactory radium therapy, by the technique employed in the treatment of keloids, appears to be worth while. More than one-half of the patients treated should receive definite benefit. Radium treatment of 141 patients over a period of 6 years is described. 44.6 per cent of the patients treated were not benefited, but the remainder were helped.

The age of the patient, the duration of symptoms before treatment, and the number of treatments given did not seem to be factors definitely influencing the result.

GENITAL ORGANS

Carcinoma of Prostate. JOHN B. WEAR and A. P. SCHOENENBERGER. *J. Urol.*, Balt., 1948, 59, 587

The authors present an analysis of 383 cases of carcinoma of the prostate, which have been followed at the Wisconsin General Hospital, Madison Wisconsin, from 1933 to 1943 inclusive.

A comparison of the end-results following various methods of treatment is difficult since the indications for treatment were not precisely the same. Thus, a graphical presentation purporting to show the relative survival would not be a true curve since metastasis was present in 80 per cent of patients receiving one type of treatment, and in only 25 per cent of those receiving another type of treatment. With any form of treatment there will always emerge a few patients (of a group) who live for many years. It seems evident that prostatic carcinoma is extremely slow-growing in isolated instances. On the one hand the method of treatment is given unfair credit, on the other hand, we are dealing with patients of advanced age who are subject to all the degenerative diseases and even without carcinoma many of them would die of other lesions, but once the diagnosis of carcinoma is made that is given as the cause of death on the death certificate.

Seventy-seven patients had had no treatment at all or at the most only palliative treatment. Nearly all were seen prior to 1940. Usually these patients were poor surgical risks or they had advanced carcinoma without pain. They survived for an average period of 8 months following diagnosis, or 33 months from the onset of symptoms. 6 of the group lived more than 4 years from the onset of symptoms.

Twenty-one patients were treated with suprapubic cystostomy only. The patients in this group had marked obstructive uropathy and advanced renal damage. The operation did not prolong the life of the average patient and the authors believe that no great benefit was gained.

Twenty-five patients received roentgen therapy alone which was never given with intent to cure. However, some relief of the pain associated with metastatic lesions was obtained in about 50 per cent of the patients for varying lengths of time. In the future this form of therapy will be relegated to a minor role inasmuch as estrogens and orchectomy will be tried first.

In 3 cases a suprapubic prostatectomy was done following a diagnosis of benign prostatic hypertrophy. On examination of the glands removed a diagnosis of carcinoma was made.

Transurethral resection was performed in 145 patients. Only 21 per cent of this group showed metastasis on admission. They all carried over 150 c.c. of residual urine, the prostates were enlarged, and in many cases the carcinoma had spread beyond the capsule. The authors definitely feel that the average life of the patient was prolonged. They report a 5 year survival in 9 per cent of this group. 5 patients survived 5 years, three 7 years and three, 9 years.

These patients are all symptom-free. It is believed that transurethral resection has a definite place in the treatment of carcinoma and that it is the treatment of choice in patients with obstruction, in whom the lesion is too advanced for perineal enucleation.

Radical perineal prostatic resection was performed on 16 patients. Before the patient was subjected to the operation the following criteria were demanded: (1) the gland had to be freely movable (2) there could be no evidence of metastasis (3) the patient had to be a fair surgical risk and have a good life expectancy. The operation probably should not be performed after the seventh decade of life. Eight of the 16 patients are still alive. 3 of the 8 recently have had orchectomy for metastasis; the remaining 5 appear to be in excellent health although some are taking stilbestrol, without evidence of recurrence or metastasis. In the authors' opinion this operation offers the only chance of cure.

One hundred and three patients received endocrine treatment in conjunction with surgical methods. 23 patients received endocrine therapy alone. The patients who received endocrine treatment do not present a homogeneous or a closed group. The present group was unselected and the patients have been followed up. It has been observed that up to 80 per cent of patients respond to this form of treatment for varying lengths of time, some dramatically within a few days. Immediate results were more frequently noted following orchectomy, particularly the amelioration of pain. Estrogen therapy did not prove to be a useful supplement in cases of failure with orchectomy. The authors are using stilbestrol in the treatment of all lesions definitely diagnosed as carcinoma, and orchectomy is reserved for those patients who show objective evidence of metastasis. They believe, from this study that estrogenic therapy combined with transurethral resection is the operation of choice for prolongation of life and relief of pain. Early radical perineal prostatectomy is just as safe and offers the hope of cure in about 4 per cent of the patients seen.

ROBERT O. BRADLEY, M.D.

Metabolism of Estrogens in Prostatic Cancer

JAMES A. MAY and BENJAMIN F. STRAUSS. *J. Urol.*, Balt., 1948, 59, 396.

In view of the remarkably beneficial effect of estrogen therapy in patients with carcinoma of the prostate. It seemed profitable to the authors to study the capacity of these individuals to metabolize therapeutic doses of the natural estrogens. It was believed that such studies might uncover some abnormalities peculiar to patients with prostatic cancer and knowledge of their existence might be useful in the diagnosis or prognosis of the disease.

The application of the authors' procedure for the fractionation and photometric estimation of the urinary estrogens (estradiol, estrone and estril) in a small series of cases with and without carcinoma of the prostate, following the administration of single therapeutic doses of the natural estrogens, revealed (a) that there is no consistent difference in the total

estrogen excretion (b) that the presence or absence of the testes appears not to alter the total excretion of the estrogens nor the relative distribution of estradiol, estrone and estriol in the urine and (c) that the patients with carcinoma of the prostate showed a tendency to convert exogenous estrone into estriol more readily than did the patients without cancer.

FREDERICK A. LLOYD, M.D.

The Efficiency of Estrogens on Cancer of the Prostate (Die Wirkung der Oestrogene auf das Prostatacarcinom) RUDOLF GEISERDORFER, *Arch. Forsch.* 947, 197.

The author quotes Walther, whose postmortem examinations revealed an incidence of 30 per cent of cancer of the prostate after the fortieth year of age. He also states that the therapeutic means of transurethral resection, deep roentgen therapy and radical operation did not come up to expectations. In a review of chiefly Anglo-American bibliography he compiles 1,003 cases in which the patients were treated with estrogens, to which he adds several hundred cases, of Palazzoli in which estrogen therapy was employed.

The author reports his own experience with 20 cases observed since 1944, first at the Surgical University Clinic of Heidelberg and then at Frankfurt. In 3 of his cases castration was performed; 1 patient was treated with implantation of 50 mgm. of ovocyclin (25 mgm. in each rectus muscle); 6 patients were treated with injections of cyren B forte, first in a dosage of 1 ampule (55 mgm.) every third day, later every second day, and eventually daily; a histological diagnosis was made in 10 cases and bony metastases were present in 3 cases. The average residual was 200 c.c. The first clinical symptoms appeared in from 6 weeks to 6 years before treatment and the average age of the patients was 66.9 years. The patients were observed over a period of from 14 days to 36 months. Additional therapeutic procedures consisted of 8 transurethral resections, 1 suprapubic prostatectomy plus electrosurgical operation, 1 suprapubic prostatectomy and transurethral resection, suprapubic cystostomy, deep roentgen therapy in 3 cases, and treatment with indwelling catheters in several cases. Eight patients died, 4 of these within the first 4 months. Only 7 patients received roentgen therapy regularly and 3 of these had been castrated. The weight increased 15 to 10 kgm. The residual decreased to 5 c.c. Some relief from dysuria was obtained in 3 cases. Local findings revealed decrease in size, softening, and recession of infiltration in 5 cases; in 5 cases the condition remained unchanged; in 5 closely observed cases the condition improved; in 3 patients and deteriorated in 2 of 8 patients with "rheumatic complaints," 5 were improved, 2 were symptom-free and in 1 patient there was no change. The general condition improved in 18 patients, and swelling and tension in the breast occurred in 7.

The author states that all available estrogen preparations have been found efficacious with the excep-

tion of pro-estrogen α -di(p-actocyphenyl)- β -phenyl-bromacethylen.

The dosage of estrogen administration by various authors per day and per week is reviewed. The total dosage of estrogen is also reviewed; it varies with different authors from 75 mgm. to 1,546 mgm. The importance and significance of regular acid phosphatase tests for proper dosage is stressed. The author compares injection therapy with oral and implantation therapy and he hopes that the latter two methods of application will eventually replace injection therapy. He mentions estrogen therapy by castration; its favorable result upon pains due to bony metastases was confirmed in 3 cases. The increase of weight due to hormone therapy is explained on the basis of castration. The decrease of pain due to bony metastases in the presence of progressive metastases is explained as a direct action upon the pain pathways. The author states that this requires further investigation. The improvement of the general condition is explained on the basis of the direct action of hormones on the primary tumor. The decrease in size, softening, and even the disappearance of nodules is confirmed. This involvement was studied histologically by Nesbit, Parnes, and Cummings, and accounts for the decrease of the residual.

The author differentiates three parts of the prostate: the first, or the regrettal, commissure which lies between the bladder and the ejaculatory ducts; the second or pregenital, commissure which lies below the ejaculatory ducts and the third or antenor commissure which is situated in front of the urethra. He calls the first the "endogland" and the second and third the "exogland." From his experimental work he reports that the exogland responds to estrogen administration with atrophy and shrinkage whereas the endogland reacts to the same substance with proliferation.

If the cancer originates from the exogland (as is usually the case according to Bibus and others) the effect of estrogen therapy is obviously self-explanatory. The cancers which resist estrogen therapy may originate in the endogland. This would concur with the experience of Huggins, of failure in 5 per cent of patients treated with estrogens. If one considers a bony metastasis as dispersed cells originating from the exogland, the efficiency of estrogen therapy on the metastasis is explainable. It is difficult to explain why estrogen therapy or the effect of castration exhausts itself after 11 to 16 months, and the author quotes Huggins, according to whom the adrenals are playing a responsible role after castration.

Finally the author compares the experience with out estrogens and with estrogens or castration, as published in the literature. The results are in favor of the estrogen and castration therapy. He concludes his remarks with the statement that a considerable prolongation of life and in a few cases apparently a true cure can be achieved by the application of estrogens in cancer of the prostate.

ERNEST BORN, M.D.

Twenty-Seven Years of Prostatic Surgery at Bellevue Hospital JOHN W. DRAPEL, *Surgery 1948*
33 515.

During the past quarter of a century many bitter arguments have been waged concerning the relative merits of the various methods of operative treatment for benign prostatic hypertrophy. Many changes have taken place in the methods used during these years of discussion and development of new operations. It seems appropriate therefore at this time to evaluate the progress which has been made. The study presented includes all patients with benign prostatic hypertrophy treated surgically at Bellevue Hospital New York between 1920 and 1946. The chief interest lies in the comparative mortality rates for the early follow-up records were inadequate for statistical analysis.

Tables and figures have been arranged to show the total number of patients with benign prostatic hypertrophy operated upon during each of the 27 years, the annual mortality rate for all operative procedures, the annual mortality rate for transurethral resection for the second stage of a two-stage prostaticotomy alone. A study was made of the 221 consecutive patients treated in the 27 year period all postmortem reports were reviewed.

It should be noted that at Bellevue Hospital no patient is denied operation if such treatment in the opinion of the staff holds any hope of success even though this practice may increase the operative mortality rate. Many comatose patients are taken to the operating rooms and a sufficient number of them survive to justify cystotomy even in the presence of coma when an indwelling catheter is not tolerated or for some reason catheterization is impossible.

A two-stage prostaticectomy has generally been considered the operation of choice in patients who are not good surgical risks and during the early years of this report a two-stage procedure was used for all patients save those in very good condition. The latter were treated by one-stage prostaticectomy or transurethral resection. At the present time patients are treated by a transurethral resection perineal, or a one-stage prostaticectomy with the exception of those with severe uremia infection and those with strictures.

The gradual lowering of the mortality rate for the second of a two-stage operation in the past 25 years cannot be attributed to great improvement in technique but must be an index of the value of the supplementary therapy.

A review of these figures gives the impression that the merits of the one-stage procedure was proved years ago and overlooked for many years until recently.

It has become the policy at Bellevue Hospital to reserve transurethral resection for glands which it is anticipated will weigh less than 50 gm. This is the only limitation of its use and often patients with severe cardiac disease and elderly debilitated pa-

tients are subjected to this procedure as a matter of choice.

Prostatectomy by the perineal route has been carried out in only 81 cases during the past 27 years and 13 of the 81 operations were done in 1946. There has been little enthusiasm for this approach to the prostate gland and there have been years in which no perineal prostatectomies were done and in other years there were only one or two. The infrequent use and unpopularity of this procedure is reflected in the mortality rate which averages 19 per cent for the 27 years an appallingly high figure.

It should be stated that 12 patients were subjected to perineal prostatectomy in 1946 by the technique advocated by Elmer Belt, without one death.

It is obvious from reviewing the records of Bellevue Hospital for the past 27 years that more patients are being subjected to prostatic surgery each year and a smaller percentage are dying as a result of their surgery. The over all mortality has dropped from 40 or 50 per cent in the early twenties, to 4.6 per cent in 1946. This is a most gratifying record and is attributable to the ingenuity industry and surgical skill of a large group of urologists who have worked during the 27 years for no greater reward.

JOHN E. KIRKPATRICK, M.D.
Misshape of Prostatic Resection. R. J. SILVERTON
Brit J U of 1948 20 2.

The author's personal conviction is that the ideal anesthetic for prostatic resection is a fairly low level of spinal analgesic cover namely up to the symphysis pubis.

Rupture of the bladder. When this occurs under any form of general anesthesia, all we are cognizant of is that some degree of shock has taken place, but the exact diagnosis of the mishap cannot be made at once. Under lumbosacral cover of spinal analgesia however immediately after extraperitoneal rupture the patient experiences pain usually in one groin or iliac fossa this pain soon spreading to the opposite side but remaining low in the abdomen although intraperitoneal rupture, severe pain is felt in the epigastric region, and the author has had a case in which both types of rupture occurred, the lower pain coming on a little earlier than the upper. On palpation great tenderness is felt in the regions named and in the case of intraperitoneal rupture distinct muscular rigidity occurs.

In cases in which the mishap is recognized at once, treatment can be instituted immediately and this is an inestimable boon, for in this way death is prevented. Pentothal should be administered intravenously and the bladder opened snappily with a retractor and the author inserted an illuminated Young's boomerang needle, but in all other cases simple cystostomy with a dePezaer drain allowed perfect healing of the bladder wall and return of the shocked patient to bed in quick time. As the accident usually occurs near the end of resection a large

plain catheter or better a Bardex bag catheter is left in the urethra. The prevesical and paravesical spaces are drained by two moderately fine rubber tubes.

Damage to the external sphincter. There is no danger to life from this mishap but the most severe cases are curable only with great difficulty. If at all, and lifelong disability to the patient may result, with worry and loss of reputation so far as the surgeon is concerned.

It is well known that the lateral lobes of the adenoma extend distally as far as, or a tiny bit beyond, the colliculus seminalis. This applies all around the circle and one must not exceed this limit whether resecting on the rectal lateral or pubic aspects of the canal, for a little beyond the colliculus is the membranous portion of the urethra with its intimately surrounding sphincter muscle.

In all cases of incontinence the patient should be instructed in the exercise of voluntarily interrupting the stream several times during each urination. Exhibition of belladonna and ephedrine may also help. In the early stages the patient should lie down a good deal and also pass urine fairly frequently to prevent too great distention of the bladder. If no improvement occurs after a few months, the patient will find it a great comfort to wear a penile incontinence clamp when up and about, for he is usually not incontinent when lying down; at least the author has not seen such a case. Moreover the patient is usually continent when sitting, and this is helped by crossing the legs. The patient is asked to wear the clamp as little as possible. When he is at home, the towel method or rubber urinal, may be convenient and prevents distention of the urethra.

In the days of perineal prostaticectomy Hugh Young described an approach by superficial perineal urethrotomy through the bulbous urethra to resect a portion of the floor of the membranous urethra, with re-suture to narrow the canal and repair the external sphincter. Another possibility is to pass a sound and approach the membranous urethra by Young's deep perineal dissection, remove a portion of its floor and close the canal again. All neighboring muscles including the anterior margins of the levatores ani may be brought together under the membranous urethra tightly, as a supporting hammock. It is theoretically safer to provide suprapubic deviation of the urine during the early convalescence after this operation, but a small catheter in the urethra should not interfere with its success. At the present time, the author would use for this purpose a 16 F Foley retention catheter to be retained for 10 days.

Stricture of the urethra. The author has seen this mishap occur in the penile portion of the urethra. The bulbous portion is normally relatively wide, and is not likely to be affected. The author has not yet seen stenosis of the membranous portion and the internal meatus is well opened up by the resection. In cases in which he has had the opportunity of inspecting and palpating the internal meatus at cystotomy later it has been found nicely open.

In patients with a small penis or a relatively narrow urethra, one should by-pass the penile urethra by resecting through a perineal urethrotomy or using the 24 F resectoscope. The latter should not be done, however unless the resectoscope lies loosely to the canal. In diagnosis, the 24 F panendoscope should not be used routinely for, if the urethra seems narrow when sounds are carefully passed, the dilatation should stop at about 18 to 20 F and a panendoscope sheath of one of these sizes should be used. If resection is then decided on, one may do it at once through perineal urethrotomy or wait 3 days or so, when the urethra should take the 24 F resectoscope easily.

Hemorrhage. The author prefers rapid resection stopping at once to coagulate all definite spurs which cause the fluid medium to turn even a moderately deep red. One should avoid cutting into the finely striated compressed true prostatic tissue for fear of awkward venous bleeding if one gets out to the true prostatic capsule. The multitude of little vessels on the vesical slope of the resected internal meatus should be coagulated carefully at the end of the operation, for they will not be controlled by a bag catheter and blood may seep slowly into the bladder later causing clots to form which may not be driven out by the gentle drip method of irrigation. These clots cause much irritation, and even vesical pain and interfere with free drainage through the catheter. Similarly, at the cut distal edge of the prostatic cavity at the level of the colliculus all vessels should be carefully coagulated otherwise a continuous and annoying seepage of blood will run down to the external meatus.

Ever since Mortensen, of Melbourne introduced to the author the idea of bag catheter hemostasis (near the end of 1945) he has considered this method indispensable to a smooth, untroubled convalescence. The best catheter is the one with a pyriform bag, and in most resections the 22 F catheter is sufficiently large. Its bag dilates up to about 40 c.c. If the resection is a large one, the 24 F catheter with bag dilating to about 70 c.c., is useful. When the catheter is inserted it is well pushed in and a continuous stream of water is kept flowing in and out then the bag is inflated to about 1 c.c., a drip is pulled right into the prostatic cavity where it remains in position without traction if inflation is completed up to the estimated capacity. About 10 ounces of water are left in the bladder, and the two outlets are spigoted. A continuous boric drip, controlled by a Murphy drip regulator is instituted immediately the patient gets to bed and the drip is regulated to a slow drip when all pink stain disappears, but is accelerated if slight bleeding is observed. The catheter is removed (after deflation of the bag) in 4 days.

Later or secondary hemorrhage is rare in these days of efficient electric and rubber bag hemostasis, but treatment is the same as that described. Sulfonamides during convalescence, with penicillin added if desired has also minimized the tendency to hemorrhage by reducing infection. JOHN A. LOFF, M.D.

Immediate Prostatectomy for Retention of Urine.

G. A. BAOOR WALTERS. *Brit. M. J.* 1948, 1, 638.

In recent times so many different procedures have been advocated for dealing with benign prostatic hypertrophy that it is becoming increasingly difficult to estimate the value of new methods of treatment. This difficulty has been simply shown by the conflicting views expressed at discussions which took place in 1946 at the Medical Society of London and at the Annual Meeting of the British Association of Urological Surgeons. It seems important therefore for surgeons employing new methods to publish their results so that their experiences may be shared by others and this reason prompted recording a small series of cases.

Admittedly it is difficult to draw conclusions from a small series of cases and, owing to the advent of new sulfonamides and penicillin the three series quoted here are not strictly comparable. However the figures shown give strong support to the theories put forward by Wilson Hey (1945) who maintains that 'postoperative uremia is due to infection and is encouraged by any method of slow decompression open drainage, or instrumentation. It has been the author's experience that patients catheterised before admission were far more apt to give trouble during their convalescence.'

If only selected cases are submitted to radical operation a low mortality rate can be obtained, but emphasis is laid on the fact that all cases are included in this report, and some were extremely sick patients and really deplorable operative risks.

The benefits of immediate prostatectomy for the patient with retention of urine are very great for he is spared prolonged, and sometimes painful, preoperative treatment and a long illness. Some notice must also be taken of the economic factors involved as the rapid recovery of patients is most necessary at the present time, when there is such a shortage of hospital beds.

Attention to details in treatment is of paramount importance, for even a comparatively trivial set back, such as a blocked catheter may have serious consequences in elderly and decrepit patients. All patients get out of bed the day after operation, and to this practice may be attributed the low incidence of chest complications. The majority of patients go home in good condition about the twelfth to the sixteenth day.

A consecutive series of 141 cases of benign prostatic hypertrophy is recorded. 138 were submitted to radical operation.

Except on very rare occasions drainage before operation, whether by catheter or suprapubic tube is not considered necessary or desirable.

There were 97 cases of retention of urine. Wherever feasible these patients were treated by immediate prostatectomy. 7 (7.2%) died. 70 were operated on for acute retention, with 4 (5.7%) deaths.

As many patients were admitted in very poor condition the results shown are considered satisfactory. It seems that the method of immediate

prostatectomy is well worthy of an extended trial.

JOHN E. KIRKPATRICK, M.D.

Retropubic Prostatectomy

OSWALD S. LOWMYER and

ALBERTO GENTILE. *J. Urol.*, Balt., 1948, 59, 581.

The authors report the results obtained in 28 patients on whom retropubic prostatectomy was performed. The technique employed was similar to that used by Millin except for the method of hemostasis and drainage of the bladder. Spinal anesthesia was used.

With the patient in the Trendelenburg position a midline suprapubic midrectus incision is made. The peritoneum and prevesical fat are drawn upward. The anterior surface of the prostate is next exposed. Gause is packed on either side of the prostate to elevate this structure. The veins lying over the anterior surface of the prostate are clamped, ligated and divided. A transverse incision is made in the prostatic capsule. The adenoma is removed by blunt dissection after the urethra has been cut near the apex of the prostate, and the vesical attachments have been severed. The posterior lip of the vesical orifice is sutured with No. 0000 chromic catgut. A No. 24F 30 c.c. Foley bag catheter is introduced through the penile urethra and brought out through the prostatic cavity. Gelfoam saturated in thrombin is placed around the bag and secured in position. The bag portion is placed in the prostatic fossa and the latter is closed with No. 1 interrupted chromic catgut sutures. The hemostatic bag is distended and the wound is closed with a small drain in the prevesical space.

Twenty-eight patients were operated upon by this method. Twelve of the patients were from 52 to 59 years of age. 8 were from 60 to 69 years. 7 were from 70 to 79 years and 1 was 82 years of age.

The smallest mass of tissue weighed 8 gm. and the largest weighed 100 gm. In 11 cases the tissue weighed from 20-39 gm. in 10 from 40 to 89 gm. and in 3 from 90 to 100 gm.

The authors state that the operation is difficult to perform when the prostatic tissue to be removed weighs less than 20 gm. Enucleation is laborious, the plane of cleavage being poorly established but the amount of capsule remaining makes closure difficult. There was no operative mortality in the 28 cases. The average postoperative hospitalization was 9.5 days. Usually the catheter is removed on the fourth postoperative day and the patient is discharged from 4 to 6 days later. Patients must be asymptomatic before they are discharged.

In 30 cases (71 per cent) the catheter was removed on or before the fourth postoperative day. The catheter was never removed until the urine was completely clear. In the authors' experience early removal of the catheter has not predisposed to the formation of a suprapubic fistula.

All patients were mobilized as early as possible more than one-half of the patients were allowed up in a chair the day after operation. In 86 per cent of the patients the Penrose drain was removed on

or before the third postoperative day. In 95.7 per cent of the patients the suprapubic wound was completely dry by the fifth postoperative day. The first two patients in whom the authors used the electrocautery for hemostasis, had profuse postoperative bleeding. In the remaining 26 cases, hemostasis was secured as previously described. Of these, 21 patients had clear urine on the second day. No case of postoperative incontinence or of retention of urine was encountered. Sexual ability is not impaired to any greater degree than after suprapubic prostatectomy.

The authors list the advantages of the retropublic method of approach but state that the method is no panacea, and suggest that the type of operation should be dictated by the nature of the lesion present. The indications and contraindications for the transurethral approach, suprapubic approach, the perineal method and the retropublic method are discussed. The report contains not only a description of the operation but also many excellent drawings.

PETER L. SCARDINO, M.D.

Retropublic Prostatectomy SAMUEL K. BACON, J.
Urol., Balt., 943, 59, 376.

The technique of retropublic prostatectomy is described and the authors' experience with this procedure in 35 cases is reviewed.

The features of the operation as described by Millin are as follows: (1) retropublic prostatectomy is an extravesical procedure; (2) it is applicable to all types of prostatic obstruction; (3) it is relatively short and shock-free; (4) it appears to be anatomic ally sound and does not endanger any important organs; (5) the whole of the obstructing tissue is removed; (6) the postoperative course is easy for the patient and attending staff; (7) the postoperative stay in the hospital seldom exceeds 3 weeks; (8) the mortality rate is singularly low.

After spinal anesthesia the bladder is lavaged and emptied. Starting over the symphysis pubis, a 3/4 to 3 inch longitudinal incision is made through the skin, subcutaneous tissue and fascia. The recti muscles are separated in the median line exposing the prevesical space. With the index fingers the loose areolar and adipose tissue and peritoneum are gently reflected upward. This maneuver readily exposes the anterior surface of the prostatic capsule. A self retaining retractor is introduced to separate the recti widely and the upper blade is attached to retain the bladder upward and posteriorly.

It is essential to study the distribution of veins on the anterior and lateral aspects of the prostate. Approximately 8 inches of 4 inch gauze is packed gently into each lateral recess of the prostate against the levator ani. Any veins inadvertently traumatized should be clamped and diathermized. The central leash of veins is underrun, with Millin's boomerang needle and ligated. The lateral group on each side is similarly treated.

A curved transverse incision, convexity downward, 1 cm. distal to the bladder neck, is made with a

Bard Parker knife or diathermy electrode through the prevesical fascia and true and false capsules down to the adenoma, which is readily recognized by its typical whitish appearance. Suction is maintained to keep the field dry and to enable the operator to clamp any bleeding vessels with Kocher forceps. The plane of cleavage between the false capsule and adenoma is established by a pair of closed curved scissors. The right index finger is introduced under the capsule, directed toward the external sphincter and swept laterally and posteriorly against the prostate. Usually the urethra separates readily from the prostate, but if it resists, it should be cut transversely at the apex of the gland. The distal extremities of the lateral lobes are turned upward through the capsular incision and grasped with a tenaculum. The dissection is continued by sponging off the capsule, trigone and bladder neck, leaving free except for a cone of mucosa the latter is then clamped and diathermized. After placing a small gauze pack into the prostatic fossa the edges are secured with Millin's T-shaped angle clamps and capsule-grasping forceps. When the pack is removed all bleeding vessels are visualized and diathermized. Keeping the field dry with an open-end suction materially assists in this procedure. The bladder neck is palpated and if it is contracted or indurated, a section is excised posteriorly. A small catheter is directed through the urethra to the prostatic fossa and guided into the bladder.

Oxygel placed in the fossa insures a more complete hemostasis. The capsule is closed with a continuous suture of No. 0 chromic catgut. A small Penrose drain is directed to the capsule and the wound is closed. Irrigation of the catheter usually reveals a clear return flow with the third syringe.

The drain is removed on the third or fourth day and the catheter on the fifth day.

FREDERICK A. LLOYD, M.D.

Retropublic Prostatectomy TERENCE MILLIN, J.
Urol., Balt., 943, 59, 367.

The author briefly reviews the history of development of the retropublic approach to the prostate and considers a few types of associated urinary tract diseases. With use of the retropublic approach apparently many of the difficulties presented by other methods of prostatectomy are overcome. Visualization of the prostatic bed is excellent. It permits the control of hemorrhage obviates the need of long uncomfortable hospitalization, suprapubic fistula and late stenosis at the bladder neck, as well as the need for excision or plastic suture of the vesical neck.

Of 50 consecutive cases, the average postoperative hospitalization was 16.5 days. Seven of the patients were handled transurethral and one was discharged with a suprapubic tube because of renal insufficiency. Three patients with carcinoma of the prostate underwent radical removal.

Of 403 patients, only 84 required second stage retropublic prostatectomy. 3 patients were discharged with permanent suprapubic tubes. One patient died

2 months later of carcinoma of the stomach 1 of the 3 had marked renal insufficiency Two additional patients died following cystostomy one from coronary thrombosis and the other in uremia. Only 9 of the 24 patients were subjected to preliminary cystostomy by the author

Renal incompetence which fails to respond to urethral catheter drainage is handled with a supra pubic tube Antibiotics now permit the use of catheter (urethral) drainage in the presence of gross infection Vesical calculi are readily extracted through the vesical neck during the course of a retropubic prostatectomy Vesical diverticula and bladder tumors offer no impediment to retropubic removal

Of a total of 1503 retropubic prostatectomies performed in clinics throughout Europe the average mortality rate was 5.3 per cent The average calyculous reaction for the fibrous prostate removal of the calcareous prostate Excision curettage or subtotal prostatectomy can be performed by this method The author has performed the calyculous operation for operable carcinoma of the prostate 9 times Other urological problems satisfactorily handled by the retropubic approach are (1) ruptured posterior urethra, i.e., torn apex of the prostate associated with fractured pelvis (2) exposure and excision of congenital prostatic valves (3) cure of incontinence in epispadias (4) some post prostatectomy obstructions (5) prostatic abscesses and (6) impacted prostatic calculi

PETER L. SCARFONE, M.D.
Ann. Surg., 1948, 127, 13.

As performed by Wildbolz, Zuckerkindl, Bismarck, Young and Thomson Walker epididymectomy consisted of high ligation of the vas through an oblique inguinal incision the extraction of the cord and testis from the scrotum via the inguinal canal, and the excision of the distal part of the vas and epididymis by dissection from above downward With this technique it is usually difficult to be certain of avoiding damage to the spermatic vessels and there has been a tendency to seek an alternative and safer method.

Heinatz (1944) described an original method by which the epididymis was dissected free after the tunica vaginalis was opened through a scrotal incision and he used a nest maneuver to ensure that the spermatic vessels were separated from the vas and kept out of danger A small incision was made through the tunica albuginea on the vas and the director was inserted on the medial side of the testis adjacent to it were divided with the scalpel. The director lies within the internal spermatic fascia and the vas and spermatic vessels are preserved deep to it In the early tuberculous epididymis this method is sound but if advanced cancer is present there is an obvious disadvantage in opening the tunica albuginea so close to an infected area.

An attempt was made therefore, to devise a technique by which these disadvantages could be avoided but in which the approach and maneuver of Heinatz could be utilized The operation to be described has been evolved has proved satisfactory in practice and is now employed by the author as routine

A transverse incision 2 in. long is made through the scrotal skin and dartos of the affected side. If a discharging sinus is present this is included in the incision and the track dissected out. The three spermatic fasciae are divided in the line of the incision and the tunica vaginalis and the latter is opened sufficiently to allow the testis to be everted from it The fasciae are not separated from the tunica which is turned inside out however the spermatic fascia so as to allow the cord and its coverings above the tunica to be brought into view outside the wound With the testis lying on its medial side a pair of straight Mayo scissors are pushed into the sinus of the epididymis and on up the cord until the points present at a level above the upper limit of the tunica. The fasciae overlying the separated scissor points are divided with a scalpel, and the edges nearest the scissor blades and the two branches to the epididymis are isolated ligated and divided With the scissor in position, the tail of the epididymis is picked up and the tail of the epididymis is already separated free from the testis portions of the tunica and overlying fasciae attached to the epididymis are then separated from the remain der as far up as the original incision on the scissor points, bleeding vessels (branches of the funicular artery) being picked up with hemostats as they are cut. The sole remaining attachment is the vas itself which is followed as far as possible up the cord before it is divided. A running suture then closes the spermatic fasciae and the skin and dartos are closed with a small drain

MISCELLANEOUS

Intestinal Distention R. CAMPBELL BEGG, J. Urol.
 Balt. 1948, 59, 358.

In the present article the author states that "Urologists rarely write about abdominal distention but it has given most of us a headache from time to time As a class we are rather allergic to so are glad to get out as soon as possible. We are however abdominal surgeons even if for the most part, extraperitoneal ones and as such have to face up to the problem of postoperative gas pains, meteorism and adynamic ileus The first are distinctly unpleasant in our work, as they have to face do and Orr (1942) at the very time we wish to maintain and foster it. The elimination of such post operative incidents is therefore well worthy of our attention and incidentally should point the way to

or before the third postoperative day. In 93.7 per cent of the patients the suprapubic wound was completely dry by the fifth postoperative day. The first two patients in whom the authors used the electrocautery for hemostasis had profuse postoperative bleeding. In the remaining 36 cases, hemostasis was secured as previously described. Of these, 31 patients had clear urine on the second day. No case of postoperative incontinence or of retention of urine was encountered. Sexual ability is not impaired to any greater degree than after suprapubic prostatectomy.

The authors list the advantages of the retropubic method of approach but state that the method is no panacea and suggest that the type of operation should be dictated by the nature of the lesion present. The indications and contraindications for the transurethral approach, suprapubic approach, the perineal method and the retropubic method are discussed. The report contains not only a description of the operation but also many excellent drawings.

PETER L. SCARDINO, M.D.

Retropubic Prostatectomy SAMUEL E. BACON, J.
Urol. Balt., 943, 59, 376.

The technique of retropubic prostatectomy is described, and the author's experience with this procedure in 33 cases is reviewed.

The features of the operation as described by Millin are as follows: (1) retropubic prostatectomy is an extravesical procedure; (2) it is applicable to all types of prostatic obstruction; (3) it is relatively short and shock free; (4) it appears to be anatomically sound, and does not endanger any important organs; (5) the whole of the obstructing tissue is removed; (6) the postoperative course is easy for the patient and attending staff; (7) the postoperative stay in the hospital seldom exceeds 2 weeks; (8) the mortality rate is singularly low.

After spinal anesthesia the bladder is lavaged and emptied. Starting over the symphysis pubis a 2½ to 3 inch longitudinal incision is made through the skin, subcutaneous tissue and fascia. The recti muscles are separated in the median line, exposing the prevesical space. With the index fingers the loose areolar and adipose tissue and peritoneum are gently reflected upward. This maneuver readily exposes the anterior surface of the prostatic capsule. A self-retaining retractor is introduced to separate the recti widely and the upper blade is attached to retain the bladder upward and posteriorly.

It is essential to study the distribution of veins on the anterior and lateral aspects of the prostate. Approximately 8 inches of 4 inch gauze is packed, gently into each lateral recess of the prostate against the levator ani. Any veins inadvertently traumatized should be clamped and diathermized. The central leash of veins is underrun, with Millin's boomerang needle and ligated. The lateral group on each side is similarly treated.

A curved transverse incision, convexity downward 1 cm. distal to the bladder neck, is made with a

Bard Parker knife or diathermy electrode through the prevesical fascia and true and false capsules down to the adenoma, which is readily recognized by its typical whitish appearance. Suction is maintained to keep the field dry and to enable the operator to clamp any bleeding vessels with Kocher forceps. The plane of cleavage between the false capsule and adenoma is established by a pair of closed curved scissors. The right index finger is introduced under the capsule, directed toward the external sphincter and swept laterally and posteriorly against the prostate. Usually the urethra separates readily from the prostate, but if it resists, it should be cut transversely at the apex of the gland. The distal extremities of the lateral lobes are turned upward through the capsular incision and grasped with a tenaculum. The dissection is continued by sponging off the capsule, trigone and bladder neck, leaving it free except for a cone of mucosa, the latter is then clamped and diathermized. After placing a small gauze pack into the prostatic fossa the edges are secured with Millin's T-shaped angle clamps and capsule-grasping forceps. When the pack is removed all bleeding vessels are visualized and diathermized. Keeping the field dry with an open-end suction materially assists in this procedure. The bladder neck is palpated, and if it is contracted or indurated, a section is excised posteriorly. A small catheter is directed through the urethra to the prostatic fossa and guided into the bladder.

Oxycel placed in the fossa insures a more complete hemostasis. The capsule is closed with a continuous suture of No. 0 chromic catgut. A small Penrose drain is directed to the capsule and the wound is closed. Irrigation of the catheter usually reveals a clear return flow with the third syringe.

The drain is removed on the third or fourth day and the catheter on the fifth day.

FREDERICK A. LLOYD, M.D.

Retropubic Prostatectomy THORNDYK MILLIN, J.
Urol. Balt., 943, 59, 367.

The author briefly reviews the history of development of the retropubic approach to the prostate and considers a few types of associated urinary tract diseases. With use of the retropubic approach, apparently many of the difficulties presented by other methods of prostatectomy are overcome. Visualization of the prostatic bed is excellent. It permits the control of hemorrhage, obviates the need of long uncomfortable hospitalization, suprapubic fistula, and late stenosis at the bladder neck, as well as the need for excision or plastic suture of the vesical neck.

Of 50 consecutive cases, the average postoperative hospitalization was 16.6 days. Seven of the patients were handled transurethrally and one was discharged with a suprapubic tube because of renal insufficiency. Three patients with carcinoma of the prostate underwent radical removal.

Of 403 patients, only 24 required second stage retropubic prostatectomy; 3 patients were discharged with permanent suprapubic tubes; one patient died

3 months later of carcinoma of the stomach 3 of the patients died following cystostomy one from a coronary thrombosis and the other in uremia. Only 9 of the 24 patients and the other in uremia. Only 9 patients were subjected to preliminary

Renal incompetence which fails to respond to ureteral catheter drainage is handled with a supra pubic tube. Antibiotics now permit the use of catheter (urethral) drainage in the presence of gross infection. Vascular calculi are readily extracted through the vesical neck during the course of a retropubic prostatectomy. Vesical diverticula and bladder tumors offer no impediment to retropubic removal.

Of a total of 1503 retropubic prostatectomies performed in clinics throughout Europe the average mortality rate was 5.3 per cent. The author advocates transurethral resection for the fibrous prostate or median bar but the retropubic approach for the removal of the calculeous prostate. Excision prostatic by this method. The author has performed the radical retropubic operation for operable carcinoma of the prostate 9 times. Other urological problems satisfactorily handled by the retropubic approach are (1) ruptured posterior urethra (2) torn apex of the prostate associated with fractured pelvis (3) cure of incontinence in congenital prostatic valves prostatectomy obstructions (4) some post prostatectomy obstructions (5) prostatic abscesses and (6) infected prostatic calculi.

PETER L. SCARDINO, M.D.

Epididymectomy: An Alternative Technique. Ann Roy Milner, *Brit J Urol* 1943, 10: 13.

As performed by Wildbois, Zuckerkandl, Marion High Young and Thomson-Walker epididymectomy consisted of high ligation of the vas through an oblique inguinal incision the extraction of the cord and testis from the scrotum via the inguinal canal, and the excision of the distal part of the vas and epididymis by dissection from above downward. With this technique it is usually difficult to be certain of avoiding damage to the spermatic vessels and there has been a tendency to seek an alternative and safer method.

Heidatz (1934) described an original method by which the epididymis was dissected free after the tunica vaginalis was opened through a scrotal incision and he used a neat maneuver to ensure that the spermatic vessels were separated from the vas and kept out of danger. A small incision was made through the tunica albuginea on the medial side of the testis adjacent to the body of the epididymis. The director was inserted and pushed up the scrotal pel. The director lies within the internal spermatic fascia and the vas and spermatic vessels are preserved deep to it. In the early tuberculous epididymis this method is sound but if advanced calcation is present there is an obvious disadvantage in opening the tunica albuginea so close to an infected area.

An attempt was made therefore to devise a technique by which these disadvantages could be avoided but in which the approach and maneuver of Heidatz could be utilized. The operation to be described has been evolved has proved satisfactory in practice and is now employed by the author as routine.

A transverse incision 3 in. long is made through the scrotal skin and dartos of the affected side. If a discharging sinus is present this is included in the incision and the track dissected out. The three spermatic fasciae are divided in the line of the incision which displays the tunica vaginalis and the latter is opened sufficiently to allow the testis to be everted from it. The fasciae are not separated from the tunica which is turned inside out however the spermatic fascia is separated from the external inguinal ring above the tunica so as to allow the cord and its coverings above the tunica to be brought into view outside the wound. With the testis lying on its medial side a pair of straight Mayo scissors are pushed into the sinus of the epididymis and on up the cord until the points present at a level above the upper limit of the tunica. The fasciae overlying the separated scissor points are divided with a scalpel and the edges retracted the spermatic artery can then be seen beneath the scissor blades and the two branches to the epididymis are isolated, ligated and divided. With the scissors in position, the tail of the epididymis is already separated by the scissors. Those portions of the tunica and overlying fasciae attached to the epididymis are then separated from the remainder as far up as the original incision on the scrotal points, bleeding vessels (branches of the funicular artery) being picked up with hemostats as they are cut. The sole remaining attachment is the vas itself which is followed as far as possible up the cord before it is divided. A running suture then closes the spermatic fasciae and the skin and dartos are closed with a small drain.

MISCELLANEOUS

Intestinal Distention. R. CAMPBELL BEGG, *J Urol* Balt. 1948 59: 358.

In the present article the author states that "Urologists rarely write about abdominal distention, but it has given most of us a headache from time to time. As a class we are rather allergic to so are glad to get out of it as soon as possible. We however abdominal surgeons even if for the most part, extraperitoneal ones and, as such have to face up to the problem of postoperative gas pains metroram and adynamic ileus. The first are distinctly unpleasant the last two are dangerous (Schneider and Orr 1942) at the very time we wish to maintain and foster it. The elimination of such postoperative incidents is therefore well worthy of our attention and incidentally should point the way to

the treatment of other forms of distended bladder and more particularly with anuria and uremia.

Most of us have learned, in the course of the years, that the gases of distention do not arise from food fermentation. They are the wrong kind of gases for that. Accordingly, the preoperative purgative and enema so beloved by nurses of the old school, have lost in popularity but still linger on from tradition rather than logic. More tenacious still is the idea that drinks should be encouraged, if not forced after urological operations, and this brings me to the very essence of my chosen subject. My thesis is that gas pains and distention, these evil harbingers of adynamic ileus, may be completely obliterated provided nothing whatever is given by mouth or rectum during the inevitable postoperative nonperistaltic period. This method has been practiced now for 10 years and has induced many of my surgical and gynecological colleagues to adopt it after appendectomies, hysterectomies, gastric and intestinal resections, and indeed all other types of abdominal operation. Many hundreds of urological and abdominal cases have thus come under observation.

"The typical postoperative course of a case handled in this way follows a very definite pattern. On his return to bed the patient has a cannula inserted into one of the veins on the dorsum of the hand, and all fluid, electrolytes, blood, protein and drug requirements, with the exception of hypodermics, are given through this. At an early stage, he is allowed to rinse out his mouth with water at room temperature, but no ice-water cracked ice, chewing gum, pineapple or any of the other popular thirst palliatives is allowed. The abdomen remains flat and comfortable but no sounds whatever are heard on auscultation. The nonperistaltic, refractory or silent period has set in, and may last for 6 hours to 4 days according to the nature of the operation, the preparation and medication which preceded it, the length of time that it occupied and the type of anesthetic given. When this silent stage terminates the patient may be conscious of intestinal activity and borborygmi can be heard in the upper abdomen with the naked ear or the stethoscope. In the course of 2 or 3 hours these sounds become generalized and flatus is passed per rectum. There is no discomfort of any sort accompanying this renewed activity in contrast to the irregular contractions and gas pains which herald the first appearance of peristalsis if fluids have been given. In fact, once the refractory period has come to an end, the gastrointestinal tract can cope, if need be with an ordinary meal, and even purgatives and enemas, though undesirable, have little untoward effect. The bowels move naturally on the fifth postoperative day or with the help of mild laxative pills on the sixth.

"The same story can be told after any operation provided mechanical obstruction is absent. Even with the onset of peritonitis, a condition rare in urological work, there may be little if any distention. One point that requires emphasis is the futility of setting a fixed time limit after which fluids may be

given. The termination of the nonperistaltic phase is easily recognizable by the nursing staff and the deleterious results of drinks and enemas are the same throughout, whether given at the beginning or towards the end. The nurse in charge should be warned that a thirsty patient may say he has passed flatus in order to be allowed fluids prematurely and should rely entirely on her own observations.

As in our cases the strict regime was rather revolutionary it was violated in some instances and gave the opportunity for several interesting observations. A single ounce of water swallowed on the second day after phelolithotomy initiated a progressive process of distention. A relieving nurse gave an enema to a nephrectomy case on the third day before peristalsis had recommenced. The result was a "blow-up" which kept the staff busy for 5 days before the patient was out of danger. Cracked ice sucked by a man for 1 hour only shortly after he had undergone an operation for hydronephrosis due to an aberrant vessel, produced an almost fatal adynamic ileus, finally relieved on the eighth postoperative day by the subcutaneous injection of 2 g. mgm. (5 ampoules) of prostigmin given as a single dose. This confirmed incidentally, that the term "paralytic ileus" is a misnomer for after this large dose of prostigmin, the mountain-like abdomen collapsed like a pricked balloon, while the patient screamed with colic and spent the greater part of 12 hours productively occupied on a series of inadequate bedpans! The chewing of gum, and the sucking of acid drops and pineapple squares as thirst palliatives were found to be by no means harmless. In the few early cases when these were allowed, the postoperative course was not always smooth.

A theory is suggested to explain all forms of non-mechanical intestinal distention. The gases in free solution in the blood, especially nitrogen diffuse in and out of the intestinal lumen where they serve a physiological purpose. Any excess is prevented by the tonus of the bowel muscle or disposed of by reabsorption or expulsion through the action of peristalsis. When the latter is inhibited, as during and after abdominal operations, intraperitoneal or extraperitoneal, the bowel closes down on its contents and in virtue of the unimpaired high tonus which keeps the lumen at a minimum, resists the partial pressure of the blood nitrogen which would otherwise cause dilation. Should the tonus be lowered by injury or reflex action, resistance to the inflow of gases is diminished. The latter then enter and cause distention.

The entry of any fluid or food into the stomach during the nonperistaltic period which follows all abdominal operations initiates a reflex by which the tonus of the bowel is lowered making distention possible and inevitable. The condition so produced is irreversible until the return of active peristalsis, which is itself delayed by the presence of distention. Distention once begun tends to be progressive the bowel attempting step by step to relieve strangulating pressure on its blood supply.

Preoperative purgatives and enemas disturb intestinal balance and tend to prolong the postoperative refractory phase. Gas pains, meteorism and/or adynamic ileus need never occur following urological or other abdominal operations provided mechanical obstruction of the gut is absent, no fluid food or drug is given by mouth, and no enemas are administered throughout the entire postoperative period.

The practical application of the above principles is discussed

Epithelial Metaplasia
Ass: 1948, 136 824

The finding of tissue cells of another type than those normally found in an organ of the body is always intriguing and the explanation of such an occurrence presents many difficulties. It is not strange that differences of opinion have arisen as to the exact mechanism by which such a metamorphosis of tissue cells has been produced.

Such changes are found not infrequently in the epithelium of the urinary tract, where they present an interesting urologic study. In this the author confines his attention to the changes occurring in the renal pelvis, the ureters, and the bladder. Although the epithelium of these organs possesses a different derivation embryologically that of the ureter and partly endodermal and partly mesodermal, they are all lined with transitional cell epithelium, and, except perhaps in the immediate neighborhood of the bladder outlet, true glands are not normally present.

Metamorphosis of the epithelium in these organs is of two distinct types

1 The substitution for the normal transitional cell epithelium of a stratified keratinizing epithelium and the development of leucoplakia and, by what may be regarded as a further extension of the process, squamous cell carcinoma. In this group the epithelial change is toward an epidermal type of cell.

2 The appearance in the mucosa of glandular formations with secretory properties, the so-called cystitis glandularis. In a striking parallelism to the preceding group there develops a mucin-secreting adenocarcinoma. In this group the change is toward an ectodermal type in which is found an epithelium resembling that of the large bowel.

Leucoplakia of the renal pelvis, ureters and bladder and cystitis (pyelitis and ureteritis) glandularis are the result of epithelial metaplasia in response to a call for altered function, or at least as the result of altered environment. These metaplasias are commonly associated with chronic, long-standing irritation or infection.

Leucoplakia may follow vitamin A deficiency. In this condition it is not secondary to an infection. The extent and intensity of the metaplastic process is in direct relation to the intensity and duration of the inciting factors.

Both conditions are potentially malignant. They may develop a malignant character by a further extension of the metaplastic process into squamous cell carcinoma and mucinous adenocarcinoma respectively.

Both types of cancer may develop primarily by acceleration or intensification of the metaplastic process. It is possible that the epithelial changes may be reversible.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Salmonella Osteomyelitis; Report of a Case with Salmonella Schottmuelleri as the Etiologic Agent. ROBERT C. ABRAMS and FREDERICK O. GARDNER. *U S Nav M Bull* 1948, 48, 300.

Osteomyelitis due to any of the *Salmonella* group is a rarity according to a review of the literature. *Salmonella schottmuelleri* is the organism present as proved by culture and agglutination to an involvement of the lumbosacral spine reported by Ecker-Kuehn, and Recroft who found 3 other cases in the literature.

The case reported presented multiple foci, with unusual freedom from symptoms and rapid healing.

A 9 year old negro seaman was seen first in January, 1946 he had an acute febrile episode, pain in both humeri and 34000 white blood count. Blood culture was reported normal. No roentgenograms were taken. After 8 days of penicillin therapy the fever and tenderness gradually subsided and the patient returned to duty after 26 days.

On February 20, a febrile episode occurred with pain in the right hip and was treated with penicillin and sulfadiazine, and by traction on the right leg. A roentgenogram of the hip showed no changes from normal.

By March 12 when the patient returned to the mainland, he was in acute pain and roentgen findings confirmed a diagnosis of acute osteomyelitis of the right femoral head. Surgical drainage released gray, thin, watery pus, and after 5 days of sulfadiazine and penicillin treatment the patient was afebrile. The wound was healed by March 28.

Blood and pus from the hip revealed gram-negative rods on culture which were thought to be contaminants and the cultures were destroyed.

Further roentgen studies revealed varying stages of involvement in both humeri, radii, tibiae, femora and the right hip joint. A biopsy of the right humerus was done solely to obtain a pure culture of the organism which, as well as serum agglutinations, was positive for *Salmonella schottmuelleri*.
